Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

*To my wife, Amy, who gives me love, inspiration,
and unwavering support and to our children,
Michelle, Eric, Nicholas, and Amanda.
They provide us with unlimited pleasure.*

FWS

*To Martha, my loving wife, and to my children,
Alexander and his wife Erika, to Sara, Daniel,
Elizabeth, and to my grandson Matthew who keeps
reminding us of the important things in life.
Thank you.*

PJD

*To my mother, Anne Parkhurst, and my wife,
Donna, and our children, Whit, Kate, and Maggie:
I am very appreciative and grateful for the guidance,
love, and support; gives meaning to all of what I do.
To my patients: the inspiration to work hard and do
better every day.*

CONTRIBUTORS

Brian G. Abbott, MD

Associate Professor of Medicine
Cardiovascular Institute
Warren Alpert Medical School of Brown University
Providence, Rhode Island

J. Dawn Abbott, MD

Associate Professor of Medicine
Director, Interventional Cardiology
Fellowship Training Program
Warren Alpert Medical School of Brown University
Interventional Cardiologist
Rhode Island Hospital
Providence, Rhode Island

David H. Adams, MD

Professor and Chairman
Department of Cardiovascular Surgery
The Mount Sinai Medical Center
New York, New York

Talal Al-Atassi, MD, CM, MPH

Chief Resident
Division of Cardiac Surgery
University of Ottawa Heart Institute
Ottawa, Ontario, Canada

Ali Al-Dameh, MD

Clinical Fellow in Thoracic Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Mark S. Allen, MD

Professor of Surgery
Thoracic Surgery
Mayo Clinic
Rochester, Minnesota

Nasser K. Altorki, MB, BCh

Professor of Cardiothoracic Surgery
Weill Cornell Medical College
Chief, Division of Thoracic Surgery
Cardiothoracic Surgery
New York Presbyterian Hospital/Weill Cornell
Medical College
New York, New York

Jatin Anand, MD

Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Cardiovascular Research
Center for Cardiac Support
Texas Heart Institute
Houston, Texas

Robert H. Anderson, BSc, MD, FRC Path

Emeritus Professor
Institute of Child Health
University College
London, United Kingdom;
Visiting Professor
Division of Pediatric Cardiology
Medical University of South Carolina
Charleston, South Carolina;
Visiting Professor
Institute of Human Genetics
Newcastle University
Newcastle Upon Tyne, United Kingdom

Masaki Anraku, MD, MSc

Assistant Professor
Department of Thoracic Surgery
Graduate School of Medicine
The University of Tokyo
Tokyo, Japan

Anelechi C. Anyanwu, MD

Professor and Vice Chairman
Department of Cardiovascular Surgery
The Mount Sinai Medical Center
New York, New York

Amit Arora, MD

Department of Cardiovascular Surgery
The Mount Sinai Medical Center
New York, New York

Erle H. Austin, III, MD

Professor and Vice Chairman
Department of Cardiovascular and Thoracic Surgery
University of Louisville
Chief, Cardiothoracic Surgery
Kosair Children's Hospital
Louisville, Kentucky

Eric H. Awtry, MD

Associate Professor of Medicine
 Boston University School of Medicine
 Vice Chair for Clinical Affairs
 Division of Cardiology
 Boston Medical Center
 Boston, Massachusetts

Emile A. Bacha, MD, FACS

Chief, Division of Cardiothoracic and Vascular Surgery

Edith M. Marom, MD

Professor
Department of Diagnostic Imaging
The University of Texas MD Anderson Cancer Center
Houston, Texas

Audrey C. Marshall, MD

Chief, Invasive Cardiology
Boston Children's Hospital
Boston, Massachusetts

Mauricio Perez Martinez, MD

Division of Thoracic Surgery
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

Christopher E. Mascio, MD

Assistant Professor of Clinical Medicine
Perelman School of Medicine
University of Pennsylvania
Pediatric Cardiothoracic Surgeon
Division of Cardiothoracic Surgery
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

David P. Mason, MD

Chief, Thoracic Surgery and Lung Transplantation
Department of Thoracic Surgery
Baylor University Medical Center
Dallas, Texas

Douglas J. Mathisen, MD

Chief of Thoracic Surgery
Massachusetts General Hospital
Boston, Massachusetts

Kenneth L. Mattox, MD, FACS

Professor of Surgery
Division of Cardiothoracic Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas

Robina Matyal, MD

Associate Professor of Anaesthesiology
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

James D. McCully, PhD

Associate Professor of Surgery
Harvard Medical School
Department of Cardiac Surgery
Boston Children's Hospital
Boston, Massachusetts

Robert J. McKenna, Jr., MD

Director, Thoracic Surgery
Surgery
Cedars-Sinai Medical Center
Los Angeles, California

Ciaran McNamee, MD

Instructor in Surgery
Harvard Medical School
Associate Surgeon
Brigham and Women's Hospital
Boston, Massachusetts

Jeffrey D. McNeil, MD

Colonel, U.S. Air Force
Chief, Cardiothoracic Surgery Service
San Antonio Military Medical Center
San Antonio, Texas
Clinical Assistant Professor, Cardiothoracic Surgery
University of Texas Health Science Center, San
Antonio
San Antonio, Texas

Lorenzo Menicanti, MD

Chief of Cardiac Surgery
IRCCS Policlinico San Donato
Milan, Italy

Carlos A. Mestres, MD, PhD, FETCS

Senior Consultant
Department of Cardiovascular Surgery
Hospital Clinico
University of Barcelona
Barcelona, Spain;
Cardiothoracic and Vascular Surgery
Heart and Vascular Institute
Cleveland Clinic Abu Dhabi
Abu Dhabi, United Arab Emirates

Bret A. Mettler, MD

Assistant Professor
Division of Pediatric Cardiac Surgery
Vanderbilt University School of Medicine
Department of Cardiac Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Bryan Fitch Meyers, MD, MPH

Patrick and Joy Williamson Professor of Surgery
Chief, Thoracic Surgery
Washington University School of Medicine
St. Louis, Missouri

Stephanie Mick, MD

Cardiovascular Surgeon
Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Cleveland, Ohio

Tomislav Mihaljevic, MD

Chief of Staff and Chairman of the Heart and Vascular
Institute
Cleveland Clinic Abu Dhabi
Abu Dhabi, United Arab Emirates;
Attending Surgeon
Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Professor of Surgery
Cleveland Clinic Lerner College of Medicine at Case
Western University
Cleveland, Ohio

Carmelo A. Milano, MD

Professor of Surgery
Cardiovascular and Thoracic Surgery
Duke University
Durham, North Carolina

D. Craig Miller, MD

Thelma and Henry Doelger Professor of
Cardiovascular Surgery
Department of Cardiovascular Surgery
Stanford University School of Medicine
Department of Cardiothoracic Surgery
Stanford University Medical Center
Stanford, California

Daniel L. Miller, MD, FACS

Clinical Professor of Surgery
Georgia Regents University
Chief, General Thoracic Surgery
WellStar Health System
Mayo Clinic Care Network
Marietta, Georgia

Meagan M. Miller, RN, BSN

Vanderbilt University Medical Center
Nashville, Tennessee

John D. Mitchell, MD

Courtenay C. and Lucy Patten Davis Endowed Chair
in Thoracic Surgery
Professor and Chief, Section of General Thoracic
Surgery
Division of Cardiothoracic Surgery
University of Colorado School of Medicine
Aurora, Colorado

Mario Montealegre-Gallegos, MD

Department of Anaesthesia
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Neal G. Moores, MD

Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Cleveland, Ohio

Charles E. Murphy, MD

Assistant Professor of Surgery
Division of Cardiovascular and Thoracic Surgery
Duke University School of Medicine
Duke University Medical Center
Durham, North Carolina

Raghav A. Murthy, MD

Department of Cardiovascular & Thoracic Surgery
University of Texas Southwestern Medical Center
Dallas, Texas

Sudish C. Murthy, MD, PhD

Section Head, General Thoracic Surgery
Surgical Director, Center for Major Airway Disease
Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Cleveland, Ohio

Sacha Mussot, MD

Hôpital Marie Lannelongue
Service de Chirurgie Thoracique, Vasculaire et
Transplantation Cardiopulmonaire
Le Plessis Robinson, France

Yoshifumi Naka, MD, PhD

Professor of Surgery
Columbia University College of Physicians and Surgeons
Attending Surgeon
New York–Presbyterian Hospital
New York, New York

Meena Nathan, MD, FRCS

Instructor in Surgery
Harvard Medical School
Staff Cardiac Surgeon
Department of Cardiac Surgery
Boston Children's Hospital
Boston, Massachusetts

Kurt D. Newman, MD

President and Chief Executive Officer
Children's National Medical Center
Washington, DC

Chukwumere Nwogu, MD

Associate Professor
Department of Thoracic Surgery
Roswell Park Cancer Institute
Buffalo, New York

Kirsten C. Odegard, MD

Associate Professor
Department of Anesthesiology, Perioperative and Pain Medicine
Boston Children's Hospital
Boston, Massachusetts

Daniel S. Oh, MD

Assistant Professor of Surgery
Division of Thoracic Surgery
University of Southern California
Los Angeles, California

Richard G. Ohye, MD

Professor of Cardiac Surgery
University of Michigan
Ann Arbor, Michigan

Mark W. Onaitis, MD

Associate Professor of Surgery
Department of Surgery
Division of Cardiovascular and Thoracic Surgery
Duke University School of Medicine
Duke University Medical Center
Durham, North Carolina

Aleksandra Ostojic, MSc

Division of Cardiac Surgery
University of Ottawa Heart Institute
Department of Cellular and Molecular Medicine
University of Ottawa
Ottawa, Ontario, Canada

Harald C. Ott, MD

Division of Thoracic Surgery
Massachusetts General Hospital
Boston, Massachusetts

Maral Ouzounian, MD, PhD

Assistant Professor of Surgery
University of Toronto
Cardiovascular Surgeon
Division of Cardiovascular Surgery
University Health Network
Toronto General Hospital
Toronto, Ontario, Canada

Khurram Owais, MD

Department of Anaesthesia
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Massimo Padalino, MD, PhD

PREFACE

Since its beginning as a specialty to treat tuberculosis and empyema, thoracic surgery has undergone constant change. Indeed, much has evolved in the fields of adult and pediatric cardiovascular and thoracic surgery even since our last edition. Our new ninth edition contains the latest information on the diagnosis and treatment of disease of the thorax. Especially in such areas as repair of aortic and mitral valvular disease, intervention for congenital heart disease, minimally invasive thoracic and cardiac surgery, surgical treatment of arrhythmias, and endovascular treatment of aortic disease, the field has markedly transformed. As with the previous editions, many of the same authors were asked to update their chapters, but some chapters have been added or eliminated and many others have been completely rewritten. Often new authors were chosen not based on poorly written previous chapters but to provide a novel perspective. We hope that the ninth edition will be received with the same enthusiasm as the last.

Several years ago, we lost one of the former editors of this textbook and a giant in the field of surgery, Dr. David Sabiston. We are fortunate to still have with us another editor, Dr. Frank Spencer. Dr. Spencer is not only one of the true pioneers in our specialty but a great mentor to many in our field. We are all indebted to both Dr. Sabiston and Dr. Spencer for their innumerable contributions to the field of surgery.

Finally, we would like to thank our families for providing immeasurable support not only for this textbook but for our entire careers.

Frank W. Sellke
Pedro J. del Nido
Scott J. Swanson

CONTENTS

VOLUME ■ ONE

SECTION 1 THORACIC SURGERY

PART A EVALUATION AND CARE, 2

- 1 ANATOMY OF THE THORAX, 3
Cynthia S. Chin • Rohit Shahani
- 2 RADIOLOGIC IMAGING OF THORACIC ABNORMALITIES, 26
Jeremy J. Erasmus • Edith M. Marom • Tam T. Huynh • Edward F. Patz, Jr.
- 3 PREOPERATIVE EVALUATION OF PATIENTS UNDERGOING THORACIC SURGERY, 39
John J. Reilly, Jr.
- 4 PERIOPERATIVE CARE OF THE THORACIC SURGICAL PATIENT, 47
Elisabeth U. Dexter

PART B ENDOSCOPY, 71

- 5 ENDOSCOPIC DIAGNOSIS OF THORACIC DISEASE, 72
Leah M. Backhus • Aaron M. Cheng • Douglas E. Wood
- 6 ENDOSCOPIC THERAPIES FOR THORACIC DISEASES, 79
Lara W. Schaheen • James D. Luketich

PART C TRAUMA, 99

- 7 THORACIC TRAUMA, 100
Todd C. Crawford • Clinton D. Kemp • Stephen C. Yang

PART D TRACHEA, 131

- 8 TRACHEAL LESIONS, 132
Harald C. Ott • Douglas J. Mathisen

PART E BENIGN LUNG DISEASE, 150

- 9 CONGENITAL LUNG DISEASES, 151
Raghav A. Murthy • Kemp H. Kernstine • Harold M. Burkhart • Daniel T. DeArmond

- 10 BENIGN LESIONS OF THE LUNG, 179
Doraid Jarrar • Benjamin Wei • Ayesha S. Bryant • Robert J. Cerfolio

- 11 INTERSTITIAL LUNG DISEASES, 189
Subroto Paul • Yolonda L. Colson

- 12 INFECTIOUS LUNG DISEASES, 205
John D. Mitchell

- 13 SURGERY FOR EMPHYSEMA, 227
Pamela P. Samson • Bryan Fitch Meyers

- 14 LUNG TRANSPLANTATION, 240
Lisa M. Brown • Varun Puri • G. A. Patterson

PART F LUNG CANCER, 266

- 15 SCREENING FOR LUNG CANCER: CHALLENGES FOR THE THORACIC SURGEON, 267
Brendon M. Stiles • Bradley Pua • Nasser K. Altorki

- 16 LUNG CANCER WORKUP AND STAGING, 278
Valerie W. Rusch

- 17 LUNG CANCER: SURGICAL TREATMENT, 290
Masaki Anraku • Shaf Keshavjee

- 18 LUNG CANCER: MINIMALLY INVASIVE APPROACHES, 318
Jennifer M. Hanna • Mark W. Onaitis • Thomas A. D'Amico

- 19 LUNG CANCER: MULTIMODAL THERAPY, 327
Stefan S. Kachala • David P. Mason • Sudish C. Murthy

- 20 LUNG CANCER: SURGICAL STRATEGIES FOR TUMORS INVADING THE CHEST WALL, 336
Rajeev Dhupar • Michaela Straznicka • Garrett L. Walsh

- 21 ANTERIOR APPROACH TO SUPERIOR SULCUS LESIONS, 355
Philippe G. Darteville • Sacha Mussot

PART G OTHER LUNG MALIGNANCY, 365

- 22 OTHER PRIMARY TUMORS OF THE LUNG, 366
Dustin M. Walters • David R. Jones

- 23 SECONDARY LUNG TUMORS, 383
Michael Friscia • Melissa Culligan • Joseph Friedberg

PART H**CHEST WALL, 398**

- 24** CONGENITAL CHEST WALL DEFORMITIES, 399
Konstantinos Papadakis • Robert C. Shamberger
- 25** CHEST WALL TUMORS, 430
Mark S. Allen
- 26** THORACIC OUTLET SYNDROME AND DORSAL SYMPATHECTOMY, 438
Harmik J. Soukiasian • Harold C. Urschel, Jr. • Robert J. McKenna, Jr.

PART I**PLEURA, 461**

- 27** SPONTANEOUS PNEUMOTHORAX, 462
Neal G. Moores • Karl G. Reyes • Siva Raja • David P. Mason
- 28** EMPYEMA, 467
Yaron Perry • Philip A. Linden
- 29** CHYLOTHORAX, 476
Gaetano Rocco
- 30** MALIGNANT PLEURAL AND PERICARDIAL EFFUSIONS, 481
Sai Yendamuri • Chukwumere Nwogu • Todd L. Demmy
- 31** PLEURAL TUMORS, 499
Ciaran McNamee • Jeffrey B. Velotta • David J. Sugarbaker

PART J**DIAPHRAGM, 525**

- 32** SURGERY OF THE DIAPHRAGM: A DEDUCTIVE APPROACH, 526
Carlos E. Bravo Iñiguez • Mauricio Perez Martinez • Daniel C. Wiener • Michael T. Jaklitsch
- 33** CONGENITAL DIAPHRAGMATIC HERNIA, 543
Dario O. Fauza • Jay M. Wilson

PART K**ESOPHAGUS—BENIGN DISEASE, 574**

- 34** ESOPHAGEAL ANATOMY AND FUNCTION, 575
Daniel S. Oh • Tom R. DeMeester
- 35** SURGERY FOR CONGENITAL LESIONS OF THE ESOPHAGUS, 593
A. Alfred Chahine • David Spurlock • Kurt D. Newman
- 36** SURGICAL TREATMENT OF BENIGN ESOPHAGEAL DISEASES, 607
Thomas W. Rice • Steven S. Shay • Sigurbjorn Birgisson

PART L**ESOPHAGUS—CANCER, 644**

- 37** STAGING TECHNIQUES FOR CARCINOMA OF THE ESOPHAGUS, 645
Virginia R. Litle

- 38** ESOPHAGEAL RESECTION AND REPLACEMENT, 657
Cynthia S. Chin • Philip A. Linden • Ali Al-Dameh • Scott J. Swanson

- 39** MULTIMODALITY THERAPY FOR ESOPHAGEAL CANCER, 688
Wayne L. Hofstetter • Boris Sepesi

PART M**MEDIASTINUM, 697**

- 40** MEDIASTINAL ANATOMY AND MEDIASTINOSCOPY, 698
Pamela P. Samson • Bryan Fitch Meyers
- 41** ANTERIOR MEDIASTINAL MASSES, 711
Chuong D. Hoang • Joseph B. Shrager
- 42** THE MIDDLE MEDIASTINUM, 724
Christopher W. Seder • Michael J. Liptay
- 43** THE POSTERIOR MEDIASTINUM, 729
Larry R. Kaiser
- 44** SURGICAL TREATMENT OF HYPERHIDROSIS, 745
Daniel L. Miller • Meagan M. Miller

PART N**THE FUTURE, 751**

- 45** THE MOLECULAR BIOLOGY OF THORACIC MALIGNANCIES, 752
Shawn S. Groth • Jonathan D'Cunha
- 46** INNOVATIVE THERAPY AND TECHNOLOGY, 769
Valentino J. Bianco • Arjun Pennathur • James D. Luketich

SECTION 2**ADULT CARDIAC SURGERY****PART A****BASIC SCIENCE, 786**

- 47** SURGICAL ANATOMY OF THE HEART, 787
Andrew C. Cook • Benson R. Wilcox • Robert H. Anderson
- 48** VASCULAR PHYSIOLOGY, 802
Ashraf A. Sabe • David G. Harrison • Frank W. Sellke
- 49** PHYSIOLOGY OF THE MYOCARDIUM, 818
R. John Solaro • Margaret V. Westfall
- 50** VENTRICULAR MECHANICS, 831
Mark Ratcliffe • Liang Ge • Julius Guccione
- 51** BLOOD COAGULATION, TRANSFUSION, AND CONSERVATION, 851
Jerrold H. Levy • Ian J. Welsby • Charles E. Murphy

PART B**DIAGNOSTIC PROCEDURES, 869**

- 52 CORONARY ANGIOGRAPHY: VALVE AND HEMODYNAMIC ASSESSMENT, 870**
Alexander G. Truesdell • J. Dawn Abbott
- 53 APPLICATIONS OF CARDIOVASCULAR MAGNETIC RESONANCE AND COMPUTED TOMOGRAPHY IN CARDIOVASCULAR DIAGNOSIS, 889**
Murilo Foppa • Thomas H. Hauser • Susan B. Yeon • Warren J. Manning
- 54 NUCLEAR CARDIOLOGY AND POSITRON EMISSION TOMOGRAPHY IN THE ASSESSMENT OF PATIENTS WITH CARDIOVASCULAR DISEASE, 910**
Sunit-Preet Chaudhry • Neil M. Gheewala • Brian G. Abbott
- 55 DIAGNOSTIC ECHOCARDIOGRAPHY (ULTRASOUND IMAGING IN CARDIOVASCULAR DIAGNOSIS), 927**
Rosario V. Freeman

PART C**MEDICAL- AND CATHETER-BASED TREATMENT OF CARDIOVASCULAR DISEASE, 951**

- 56 INTERVENTIONAL CARDIOLOGY, 952**
Stuart H. Chen • Duane S. Pinto
- 57 MEDICAL MANAGEMENT OF ACUTE CORONARY SYNDROMES, 973**
Robert N. Piana • Jayant Bagai
- 58 THE PHARMACOLOGIC MANAGEMENT OF HEART FAILURE, 987**
Eric H. Awtry • Wilson S. Colucci

PART D**PERIOPERATIVE AND INTRAOPERATIVE CARE OF THE CARDIAC SURGICAL PATIENT, 1008**

- 59 ANESTHESIA AND INTRAOPERATIVE CARE OF THE ADULT CARDIAC PATIENT, 1009**
Mario Montealegre-Gallegos • Khurram Owais • Feroze Mahmood • Robina Matyal
- 60 CRITICAL CARE FOR THE ADULT CARDIAC PATIENT, 1026**
Judson B. Williams • Carmelo A. Milano • Peter K. Smith
-  **61 CRITICAL CARE FOR WAR-RELATED THORACIC INJURIES, 1051**
Jeremy W. Cannon • Jeffrey D. McNeil
- 62 NEUROPSYCHOLOGIC DEFICITS AND STROKE, 1064**
John W. Hammon • David A. Stump

NERVES OF THE THORAX

Vagus and Recurrent Laryngeal Nerves
 Thoracic Sympathetic Chain
 Phrenic Nerves

The thorax is the upper part of the trunk, bounded by the diaphragm inferiorly, the thoracic inlet superiorly, and the thoracic cage between. Vital organs, such as the heart and lungs, reside completely within the thoracic cavity, and other, equally vital organs, such as the aorta and esophagus, extend into the abdominal cavity. The thorax can be divided into a right and left hemithorax, separated by the mediastinum. This chapter gives an overview of the anatomy of the thoracic cavity and its contents.

THORACIC CAGE

The cylindrical thoracic cage has two main purposes: it provides protection for the underlying organs, and the dynamic interactions of the bony and muscular components of the chest wall allow changes in respiratory volumes.

The bony thorax has two apertures, or openings: the superior thoracic aperture, often referred to as the thoracic inlet or cervicothoracic junction, and the inferior thoracic aperture (Fig. 1-14).

Thoracic Inlet

The thoracic inlet is limited by the body of the first thoracic vertebra posteriorly, the first pair of ribs and their costal cartilages anterolaterally, and the superior border of the manubrium anteriorly. Many important structures

travel through the cervicothoracic junction. Resection of malignancies (e.g., Pancoast tumor) or repair of thoracic outlet syndrome requires intimate knowledge of the anatomic relationships in this area. In this kidney-shaped inlet, the trachea is midline and behind the great vessels, and the esophagus is posterior and slightly to its left. The innominate artery arises from the aortic arch and passes posterior to the manubrium and anterior to the trachea as it travels cephalad. The right and left internal jugular and subclavian veins join behind their respective sternoclavicular joints to form the left and right brachiocephalic veins. The left brachiocephalic vein travels right to join its counterpart to form the superior vena cava. The main muscles of this region are the sternocleidomastoid and scalene muscles, and the main nerves form the brachial plexus, but the phrenic and vagus nerves also pass through this aperture.

As the margin of the aperture slopes inferoanteriorly, the apex of each lung and its covering pleura (pleural cupola) project superiorly through the lateral parts of the thoracic inlet and are covered by a piece of cervical fascia, the suprapleural membrane (Sibson fascia).

Cervicoaxillary Canal

The cervicoaxillary canal is bounded by the first rib inferiorly, the clavicle superiorly, and the costoclavicular ligament medially (Fig. 1-2). The structures that pass through this space include the subclavian vein and artery and the brachial plexus.

FIGURE 1-1 ■ **A**, Bony thorax. **B**, Inferior thoracic aperture. The vena cava enters the right hemithorax through the most cranial diaphragmatic opening, located at the level of the eighth thoracic vertebra (T8). The esophagus and vagus nerves enter the abdomen at the level of the T10 vertebra. The hiatus at T12 allows the aorta, azygos vein, and thoracic duct to pass in their respective directions.

FIGURE 1-2 ■ Cervicoaxillary canal and the structures that traverse this opening.

The subclavian artery passes over the first rib and goes between the scalenus anterior and scalenus middle muscles. Before passing over the first rib on its way out of the cervicoaxillary canal, the subclavian artery gives off branches, including the thyrocervical, internal mammary, and vertebral arteries. It becomes the axillary artery after it exits from behind the pectoralis minor muscle. Compression of this artery can lead to poststenotic dilation, stenosis, aneurysmal formation, or occlusion.

The subclavian vein travels from the arm and goes behind the pectoralis minor muscle before going between the first rib and clavicle. This space is bounded medially by the costoclavicular ligament and laterally by the scalenus anterior muscles as it inserts onto the first rib.

Compression of the vein occurs in this area and can lead to stenosis and occlusion.

The brachial plexus is composed of nerve roots from the C5 through the T1 vertebral foramina. These nerve roots join to form the superior trunk (C5 and C6), the middle trunk (C7), and the inferior trunk (C8 and T1). These trunks separate into anterior and posterior divisions that fuse again to form lateral, medial, and posterior cords of the brachial plexus. The plexus travels through the tunnel formed by the anterior and middle scalene muscles. It travels between the first rib and the clavicle and finally under the pectoralis minor muscle to gain access to the arm.

In the normal anatomy, there is ample room for each of these structures. There are four major areas in which the vessels or nerves can be compressed ([Table 1-1](#)). This topic will be discussed in detail in [Chapter 26](#).

Diaphragm

The diaphragm, at the inferior thoracic aperture, separates the thoracic cavity from the abdominal cavity. The inferior thoracic aperture, which slopes inferoposteriorly, is limited by the 12th thoracic vertebra posteriorly, the 12th pair of ribs and costal margins anterolaterally, and the xiphisternal joint anteriorly.

The diaphragm is a curved, musculotendinous sheet that is mainly convex toward the thoracic cavity. It is a continuous sheet of muscle with low posterior and lateral attachments and high anterior attachments. The central tendon is a thin but strong aponeurosis. The domes of the diaphragm descend 2 cm during quiet respiration and can travel as much as 10 cm during heightened respiratory requirements. During expiration, the right diaphragm can rise as high as the level of the nipple, whereas the left rises to a level one rib space lower. With maximal inspiration, the diaphragm flattens against the abdominal contents. The right diaphragm can flatten to the level of the 11th rib, whereas the left can flatten to the level of

TABLE 1-1 Sites and Structures Compressed in Thoracic Outlet Syndrome

Site	Description	Abnormalities	Structures Compressed
Sternal-costovertebral circle	This aperture can be narrowed by bony variations	Cervical first rib First rib Long transverse process	Subclavian artery Subclavian vein Brachial plexus
Scalene muscle triangle	The scalenus anterior and middle muscle insert on the first rib, creating a tunnel	Scalenus anterior and middle	Subclavian artery Brachial plexus
First rib, clavicular space	The neurovascular structures lie above the rib and below the clavicle	Costoclavicular ligament Clavicle First rib	Subclavian vein Subclavian artery Brachial plexus
Behind the pectoralis minor muscle	The neurovascular structures travel to and from the arm behind this muscle	Pectoralis minor Costocoracoid ligament	Subclavian vein Subclavian artery Brachial plexus

the 12th rib. The right diaphragm has to work against the liver, whereas the left needs to push only against the stomach and spleen; therefore, the right diaphragm has significantly stronger fibers than the left.

The costal diaphragm receives its blood supply from the lower five intercostal and subcostal arteries, and the central portion is supplied by the phrenic arteries. The phrenic arteries can arise directly from the aorta, above the celiac axis, as a common trunk or individually. Occasionally, they arise from the celiac or renal arteries. The sole motor supply to the diaphragm is the phrenic nerve. It also supplies sensory fibers to the parietal and peritoneal pleura overlying the diaphragm; this accounts for the diaphragmatic irritation that is sometimes interpreted as ipsilateral shoulder pain.

The diaphragm has several openings through which structures can transverse from one cavity to another (see Fig. 1-1B). The inferior vena cava hiatus lies anteriorly and to the right of the midline, at the level of vertebra T8. The right phrenic nerve travels through this hiatus, and the left phrenic nerve penetrates laterally through its own opening at the same level. The esophageal aperture is at the level of the T10 vertebra, and the right and left vagal trunks that adhere to it enter the abdomen along with the esophagus.

The aortic aperture, at the T12 vertebral level, is formed by the interdigitating fibers (median arcuate ligament) of the right and left diaphragmatic crura. The azygos and hemiazygos veins and the thoracic duct also pass through this opening.

The greater and lesser splanchnic nerves gain access to the abdominal cavity via two small apertures in each of the crura, and musculophrenic branches of the internal mammary artery penetrate the diaphragm through small apertures near its connection with the costal cartilages of ribs seven to nine.

Diaphragmatic hernias can develop through known openings, such as a hiatal hernia through the esophageal hiatus, or through congenital defects. The most common congenital abnormality is a Bochdalek hernia, in which abdominal contents go through a posterolateral defect. This abnormality is seen more commonly on the left side. A Morgagni hernia, however, occurs with a defect in the anterior aspect of the diaphragm just lateral to the xiphoid.

Bony Thoracic Cage

Sternum

The sternum or breastbone is made of cancellous bone and filled with hemopoietic marrow throughout life. The main parts, the manubrium and body, are connected by a secondary cartilaginous joint that normally never ossifies and contributes to movement of the ribs.

Up to puberty, the six segments, or sternebrae, are held together by hyaline cartilage. The central four segments fuse to form the body of the sternum between 14 and 21 years of age. The manubrium sterni (superiorly) and the xiphoid process (inferiorly) remain separate.

The manubrium receives the sternal ends of the clavicles in a shallow concave facet. The widest portion of the manubrium has bilateral costal incisurae that articulate with the first costal cartilage to form a primary cartilaginous joint. The second costal cartilage articulates with both the lower lateral ends of the manubrium and the body of the sternum, forming separate synovial joints. The muscular attachments of the manubrium include the sternocleidomastoid muscle, the sternohyoid and the sternothyroid superiorly, and the pectoralis major muscle anterolaterally. Most of the posterior surface is bare bone, which can be in contact with the brachiocephalic vein unless thymic remnants lie between.

The gladiolus, or body of the sternum, is slanted at a steeper angle than the manubrium; its articulation with that bone forms the sternal angle. Ossification of this joint, synchondrosis, in adult life can limit normal movement at this joint. The articular facets for ribs two to seven lie along the lateral border of the body of the sternum. These make single synovial joints with the costal cartilages. The facets for the sixth and seventh costal cartilages can coalesce, especially in females. The lateral border gives attachment to the anterior intercostal membrane and the internal intercostal muscles, and the pectoralis major arises anteriorly. Weak sternopericardial ligaments pass into the fibrous pericardium.

The cartilaginous xiphoid may be bifid or perforated, is of variable length, and usually ossifies in the fourth decade of life. The costoxiphoid ligaments prevent its displacement during diaphragmatic contractions.

Ribs

The 12 pairs of ribs are divided into the upper seven, which are called *true ribs* or *vertebrosternal ribs* because they form complete loops between the vertebrae and the sternum, and the lower five ribs, which fail to reach the sternum and are considered false ribs. The 8th, 9th, and 10th ribs are called *vertebrocostal* because each of their costal cartilages articulates with the adjacent rib cartilage. Ribs 11 and 12 are free-floating or *vertebral ribs* because their only articulation is with their vertebrae.

Ribs three to nine are classified as typical ribs and have a head, neck, and a shaft. The head has an upper and a lower articular facet divided by a crest for articulation with two adjacent vertebrae in synovial costovertebral joints, the lower facet articulating with the upper border of its own vertebra. The neck is flattened, with the upper border curling up into a prominent ridge—the crest. A tubercle projects posteriorly from the end of the neck and marks the junction of the neck and the body (Fig. 1-3).

MUSCLES OF THE THORAX

The muscles of the chest wall serve to protect the contents of the thoracic cavity, and they assist the movements of the thorax and upper extremities (Fig. 1-4). The 17 muscles of the chest wall are not discussed in detail here, but Table 1-2 lists them with their innervations and sites of attachments. This section focuses on muscle groups that are used in chest wall reconstruction. The latissimus dorsi, pectoralis major, serratus anterior, trapezius, rectus abdominis, and external oblique are the six major muscles that are available for reconstruction (Table 1-3).

The latissimus dorsi is the largest muscle of the thorax. It originates from the lower six thoracic spinous processes and from the lumbodorsal fiber, which is attached to the lumbar and sacral vertebrae. It also has fibers originating from the iliac crest. The muscle narrows and then inserts on the intertubercular groove of the humerus. It is sup-

plied by the thoracodorsal artery, a branch of the subscapular artery. The subscapular artery arises from the axillary artery and gives a branch to the serratus anterior muscle before supplying the latissimus dorsi. The artery can be found on the undersurface of the latissimus dorsi. The mobile arterial supply and excellent musculocutaneous collaterals allow this muscle to be moved with or without its overlying skin.

The pectoralis major muscle arises from the sternum, clavicle, and first seven ribs. It inserts on the bicipital humeral groove. It receives arterial supply from a pectoral branch of the thoracoacromial artery arising midclavicularly. It also receives some blood supply from the internal mammary, lateral intercostals, and lateral thoracic perforators. This flap is most frequently used for sternal defects.

Located between the latissimus dorsi and pectoralis major muscles is the serratus anterior muscle. This small muscle originates from the superior borders of the eighth through tenth ribs. It inserts on the tip of the scapula. Its blood supply is from a branch of the thoracodorsal artery and from the long thoracic artery. It can be used for intrathoracic purposes such as bronchial stump coverage or muscle interposition between the trachea and esophagus after a tracheoesophageal fistula repair.

The trapezius muscle arises from the occipital bone and from the spinous process of the seventh cervical vertebra and all the thoracic vertebrae. It inserts on the lateral aspect of the clavicle, the acromion process, and the spine of the scapula. It receives its blood supply from the transverse cervical artery. Although the trapezius is a large muscle, its use is limited to reconstruction of the upper thoracic cavity.

Arising from the inferior borders of the 4th through 12th ribs and inserting on the iliac crest is the external oblique muscle. It accepts blood supply from the lower thoracic intercostal arteries. Unlike the trapezius muscle, uses of the external oblique muscle are limited to the thoracic cavity below the inframammary crease.

The rectus abdominis muscle spans the entire anterior abdominal wall. It originates at the pubic crest and rises superiorly to insert on the fifth through seventh rib cartilages and xiphoid process. The superior and inferior epigastric arteries supply this vast muscle. It has been used for reconstruction of the anterior thoracic cavity, most notably after breast surgery.

Intercostal Muscles

Fibers of the intercostalis externi muscle arise from the sharp lower border of the rib above and course inferomedially (i.e., in the direction of the fingers when the hands are put into the front pockets of trousers) to the smooth upper border of the rib below. Anteriorly, it is replaced by the anterior intercostal membrane. Between the bony ribs is muscle; between the costal cartilages is membrane. In the lower spaces, the muscle interdigitates with the fibers of the external oblique (Fig. 1-5).

The intercostalis interni muscle runs from the lower costal groove of ribs 1 to 11, to the upper surfaces of ribs 2 to 12 downward and backward. Anteriorly, the muscle extends up to the sternum, but posteriorly only up to the

FIGURE 1-3 ■ Typical rib.

FIGURE 1-4 ■ **A**, Anterior view of major muscles of the chest wall. **B**, Lateral view of the muscles of right hemithorax. **C**, Dotted line indicates placement of a standard posterolateral thoracotomy. **D**, Incisional view of muscles encountered during a posterolateral thoracotomy.

TABLE 1-2 Attachments and Innervation of the Muscles of the Thoracic Wall

Muscle	Proximal Attachments	Distal Attachments	Innervation
Pectoralis major sternocostal head	Half of sternum, costal cartilages 1 to 6, aponeurosis of external obliquus muscle	Lateral lip of intertubercular sulcus of humerus	Medial pectoral nerve (C8-T1)
Pectoralis major clavicular head	Medial half of clavicle	Lateral lip of intertubercular sulcus of humerus	Lateral pectoral nerve (C5, 6, 7)
Pectoralis minor	Ribs 3 to 5	Coracoid process of scapula	Medial pectoral nerve
Subclavius	First rib	Medial clavicle	Nerve to subclavius (C5-6)
Deltoid	Lateral third of clavicle, acromion, and spine of scapula	Deltoid tuberosity of humerus	Axillary nerve (C5-6)
Serratus anterior	Angles of superior 10 ribs	Medial border of scapula	Long thoracic muscle nerve (C5, 6, 7)
Supraspinatus	Supraspinous fossa of the scapula, fascia of trapezius	Greater tubercle of the humerus	Suprascapular nerve (C5)
Infraspinatus	Infraspinous fossa	Greater tubercle of the humerus	Suprascapular nerve
Subscapularis	Costal surface of the scapula	Lesser tubercle of the humerus and its crest	Upper (C5-6) and lower (C5, 6, 7) subscapular nerve
Latissimus dorsi	Spinous processes of T7-12, L1-5, S1-3 vertebrae, posterior part of iliac crest, lower three to four ribs	Crest of the lesser tubercle and floor of the intertubercular groove of the humerus	Thoracodorsal nerve (C6-7)
Serratus posterior inferior	Spine of C6-T2 vertebrae	Angles of ribs 2 to 5	Segmental intercostal nerves
Serratus posterior superior	Spine of T11-L2 vertebrae	Lower border of ribs 9 to 12	Segmental intercostal nerves
Trapezius	Ligamentum nuchae, external occipital protuberance, thoracic vertebral spinous processes	Lateral one third of clavicle, acromion process along spine of scapula	Spinal accessory nerve
Levator scapulae	Transverse process of C1, C2, C3, C4 (cervical vertebrae)	Medial border of scapula, superior angle to base of scapular spine	Dorsal scapular nerve (C5)
Rhomboid major and minor	Spinous processes of C7-T5 and supraspinous ligaments	Medial border of scapula up to the inferior angle	Dorsal scapular nerve (C5)
Teres major	Lower lateral border of the scapula	Crest of the lesser tubercle of the humerus	Lower subscapular nerve (C5, 6, 7)
Teres minor	Mid to upper lateral border of the scapula	Greater tubercle of the humerus	Axillary nerve (C5-6)

TABLE 1-3 Arterial Supply of Muscles Used in Chest Wall Reconstruction

Muscle	Arterial Supply
Latissimus dorsi	Thoracodorsal artery
Pectoralis major	Thoracoacromial, lateral thoracic perforators, internal mammary artery, lateral intercostal artery
Serratus anterior	Thoracodorsal artery, long thoracic artery
Trapezius	Transverse cervical artery
External oblique	Lower thoracic intercostal arteries
Rectus abdominis	Superior and inferior epigastric arteries

FIGURE 1-5 ■ Spatial organization of the thoracic wall on the right side.

angles of the rib. Beyond that, it is replaced by the internal intercostal membrane, which attaches to the tubercle of each rib and vertebra.

The innermost or transversus layer is divided into three groups: the innermost intercostals (anterolateral), subcostal (posterior), and transversus thoracis (anteromedial) muscles. The fibers run downward and backward, as in the internal intercostal muscles. The subcostal muscles lie in the paravertebral gutter, are better developed inferiorly, and cross more than one space. The transversus thoracis was formerly called the *sternocostalis*, a more appropriate name. Digitations arise from the sternum bilaterally to the costal cartilages of ribs two to six.

The intercostalis intimi muscles also traverse more than one space and are better developed in the lower lateral spaces. The neurovascular bundle runs in the plane between the innermost and outer two layers. From above downward, the order is vein, artery, and nerve (mnemonic: VAN). Beyond the angle of the rib posteriorly, they are protected by the downward projection of the lower border of the rib. For a thoracotomy, the periosteum is stripped off the upper half of the rib, avoiding the lower border and the neurovascular bundle (Fig. 1-6).

As in the rest of the body, the mixed spinal nerve is formed from a dorsal and a ventral root, the dorsal root being sensory and the ventral root containing somatic motor neurons. As it emerges from the intervertebral foramina, it branches into a dorsal and a ventral ramus. The dorsal ramus of the thoracic spinal nerve supplies the paravertebral back muscles and skin of the back. The ventral ramus communicates with the sympathetic chains via white rami communicantes (postganglionic fibers). Beyond this point, the true intercostal nerve lies just superficial to the parietal pleura in the endothoracic fascia. It gains the costal groove between the innermost intercostal and the internal intercostal muscles near the angle of the rib, where a collateral branch is given off. This small branch supplies the muscles of the space, the

parietal pleura, and the periosteum of the rib. The main nerve itself has muscular branches, a lateral cutaneous branch, and a terminal anterior cutaneous branch. The lateral cutaneous branch given off along the midaxillary line gives off anterior and posterior branches to supply the skin over that space. Just lateral to the sternal margin, the terminal anterior cutaneous branches of the upper six nerves pierce the internal intercostal muscles, the external intercostal membrane, and the pectoralis major to reach skin. The lower five intercostal nerves slope downward behind the costal margin into the neurovascular plane of the abdominal wall. The subcostal or 12th thoracic nerve leaves the thorax by passing behind the lateral arcuate ligament and the subcostal artery and vein (Fig. 1-7). The cutaneous branches of each dermatome tend to overlap considerably; hence anesthesia after thoracic incisions is quite rare unless multiple intercostal nerves have been damaged. The first intercostal nerve is very small and supplies no skin, lacking both lateral and anterior cutaneous branches.

Two sets of intercostal arteries, the posterior and the anterior, are responsible for supplying the intercostal spaces. Their course and branching patterns closely conform to those of the intercostal nerves. The posterior intercostal arteries are branches of the descending thoracic aorta except in the first two spaces, where they are branches of the supreme intercostal artery, given off by the costocervical trunk of the second part of the subclavian artery. The aortic branches lie on the left side of the mediastinum; consequently, the right posterior intercostal arteries are longer, can be easily dissected in the left chest, and are seen best while operating on descending thoracic aortic aneurysms.

The anterior intercostal arteries are branches of the internal thoracic arteries from the first part of the subclavian artery. The internal thoracic artery runs anterior to the transversus thoracis and on the internal surface of the costal cartilages and the internal intercostal muscles. Approximately one fingerbreadth from the border of the sternum running vertically downward, the artery gives off two anterior intercostal arteries in each space. At the costal margin, below the sixth costal cartilage, the artery divides into the superior epigastric and musculophrenic arteries. The anterior intercostal arteries are smaller than the posterior intercostal arteries with which they anastomose and run predominantly along the lower border of each costal cartilage in the same fascial neurovascular plane. In the lower spaces, they are branches of the musculophrenic artery. There are no true anterior intercostal arteries in the last two spaces.

The internal thoracic arteries also give branches to the mediastinum, the thymus, the pericardium, and the sternum, and especially large perforating branches in the second to fourth space, the predominant supply to the lactating breast in females.

In each space, there are one posterior and two anterior intercostal veins, designated by names identical to the arteries that they accompany. The veins lie above the artery and the nerve throughout their course (i.e., VAN) in the intercostal space. The anterior veins drain into the musculophrenic and internal thoracic veins. The vein of the first space or the supreme intercostal vein, posteriorly,

FIGURE 1-6 ■ Layers of the chest wall.

FIGURE 1-7 ■ Organization of the intercostal space and the relationship of the arteries (A), veins (B), and nerves (C) to the muscle layers.

may be a tributary of the brachiocephalic, vertebral, or superior intercostal vein. The superior intercostal vein is formed by the posterior intercostal veins of the second, third, and sometimes the fourth spaces. This vein drains into the azygos vein on the right side, and on the left side it arches over the aorta, superficial to the vagus

and deep to the phrenic to open into the left brachiocephalic veins. Subcostal veins join the ascending lumbar veins and ascend on the left side as the hemiazygos and on the right side as the azygos vein draining the lower eight spaces. The blood in the hemiazygos vein drains across the midline, through median anastomoses into the azygos vein.

The internal thoracic vessels are part of the anastomotic chain that links the subclavian artery and brachiocephalic veins to the external iliac vessels. The intercostal vessels in turn connect to the descending aorta and azygos system of veins. In the presence of obstruction to flow, these anastomoses provide alternative channels for arterial and venous blood flow.

Anatomy of Breathing

Simple respiratory effort is attained mostly by diaphragmatic motion. The bony and muscular components of the thorax remain a stable cavity while the diaphragm acts as a piston. It flattens during inspiration to create negative intrathoracic pressure, resulting in expansion of the lungs. Once inspiration is complete, the diaphragm relaxes and the lung recoils to its original position. The intercostal muscles are important to prevent paradoxical motion during inspiration.

The thoracic cavity can change to meet increased respiratory needs. The accessory muscles of the chest wall help to increase intrathoracic volume during inspiration and decrease volume during expiration. In addition to the piston action of the diaphragm, the accessory muscles elevate the sternal body and xiphoid process anteriorly and superiorly. The lower ribs attached to the sternum follow this movement and therefore increase the diameter of the lower chest cavity. The manubrium of the sternum is relatively fixed, and the chest cavity at this level does not contribute significantly to increased respiratory needs. This dynamic response of the chest cavity helps to meet increasing demands for oxygenation and ventilation.

SURFACE ANATOMY

An understanding of surface anatomy enables identification of bony and prominent structures and hence the position of deeply related structures (Fig. 1-8 and Table 1-4). The chest radiograph (Fig. 1-9) is an extension of the routine physical examination.

The suprasternal notch on the superior aspect of the manubrium is palpable between the prominent medial ends of the clavicle, and it lies at the level of the lower border of the body of the second thoracic vertebra. At the lower sternal border, the palpable xiphisternum is covered by the rectus abdominis muscles. The xiphisternal joint lies opposite the body of the ninth thoracic vertebra. The sternal angle of Louis (the junction of the manubrium with the body of the sternum) is an important landmark for the description of structures inside the chest. At this level, the second costal cartilage joins the lateral margin of the sternum. The sternal angle lies opposite the lower border of the fourth thoracic vertebral

FIGURE 1-8 ■ Correlation of lungs and overlying bony structures. **A**, Anterior view. **B**, Posterior view. **C**, Right lateral view. **D**, Left lateral view. The right oblique fissure courses anteriorly at the level of the fifth rib, ending near the level of the sixth rib. The posteriorly left oblique fissure is more variable, starting at a level between the third and fifth ribs. Anteriorly, it ends consistently at the level of the fifth rib. The horizontal fissure starts anteriorly at the fourth costal cartilage and joins the oblique fissure at the level of the fifth rib.

TABLE 1-4 Surface Landmarks and Correlating Intrathoracic Structures

Landmark	Underlying Structures
Sternocleidomastoid muscle (SCM)	Internal jugular vein, cupola of pleura Internal mammary artery originates between sternal and clavicular heads of the SCM and runs 2 cm from sternal edge until the sixth costal cartilage
Right manubrial border	Right brachiocephalic vein, origin of superior vena cava, brachiocephalic artery
Manubrium	Aortic arch and origin of great vessels, left brachiocephalic vein
Left manubrial border	Left common carotid and left subclavian vessels
Angle of Louis	Trachea bifurcation Level of the fourth vertebral body
Body of sternum and third to sixth costal cartilages	Heart
At the level of the angle of Louis in the right hemithorax	Azygos vein joins superior vena cava Thoracic duct crosses midline
At the level of the angle of Louis in the left hemithorax	Aortic pulmonary window
Left third costal cartilage	Origin of aorta and pulmonary artery
Right third costal cartilage	Superior vena cava empties into right atrium
Sixth costal cartilage	Level of the eighth vertebral body Inferior vena cava and right phrenic nerve pass through the diaphragm
Left seventh costal cartilage	Tenth vertebral body Esophagus and vagal trunks pass through the diaphragm
Tip of the scapula	Seventh intercostal space

(From Butler P, Mitchell AWM, Ellis H: *Applied radiological anatomy*. Cambridge, 1999, Cambridge University Press.)

body. All other ribs are counted from this point, as the first rib is not palpable. The angle of Louis is a useful reference point for counting ribs on a computed tomography scan, and for localizing structures in the thoracic cavity. For example, the sternomanubrial joint is an important level for many structures. At this level, the azygous crosses midline to join the superior vena cava, the thoracic duct crosses from the right hemithorax to the left hemithorax on its ascent to the left neck, the trachea bifurcates into right and left main-stem bronchus, and the aorta and pulmonary artery form the aortic pulmonary window.

The clavicle articulates with the acromion process of the scapula laterally and the sternum medially. Just below the medial joint lies the fusion of the first ribs with the lateral margin of the sternum. The costal margin is the lower boundary of the bony thorax and is formed by the cartilages of the 7th, 8th, 9th, and 10th ribs and the ends of the 11th and 12th cartilages. The lowest part of the margin is the 10th rib, and it lies at the level of the third lumbar vertebra. The lower border of the pectoralis major muscle forms the anterior axillary fold. The tendon of the latissimus dorsi forms the posterior axillary fold as it passes around the lower border of the teres major muscle.

Posteriorly, the thoracic cage is covered by muscles (trapezius, latissimus dorsi, and erector spinae) and is obscured by the scapula, but there are a few useful landmarks to the rib levels. The superior angle of the scapula lies opposite the spine of the second thoracic vertebra. The transversely running spine of the scapula is easily felt and lies at the level of the third thoracic vertebra. The lower angle of the scapula overlies the seventh rib.

The first prominent spinous process in the low midline of the neck posteriorly is that of the seventh cervical vertebra, the vertebra prominens. The tip of a spinous

process of a thoracic vertebra lies posterior to the body of the next vertebra below.

The apex of the pleura extends approximately 3 cm above the medial third of the clavicle and behind the sternocleidomastoid muscle. It passes downward and medially behind the sternoclavicular joints. The left pleura, at the level of the fourth costal cartilage, deviates laterally for a variable distance from the cardiac notch. Both pleurae lie at the level of the 8th rib in the midclavicular line, at the level of the 10th rib in the midaxillary line, and at the level of the 12th rib at the paravertebral level posteriorly.

The more constant right oblique fissure of the lung follows the course of the fifth rib from the midline posteriorly, more toward its lower border. Anteriorly it ends at the costochondral junction at the level of the sixth rib. The left oblique fissure has a more variable origin from the third to the fifth rib level, but anteriorly it follows a more predictable course along the fifth rib.

The transverse or horizontal fissure (present only on the right side) is marked by a horizontal line that runs backward from the fourth costal cartilage to reach the oblique fissure at the midaxillary line at the level of the fifth rib.

The pulmonary hilum lies laterally to the sternum behind the second to fourth costal cartilages and in front of the fourth to sixth vertebral bodies. The pulmonary trunk starts behind the left costal cartilage, and it ascends to the level of the second costal cartilage before it bifurcates. The aorta also arises from the heart at the level of the left third costal cartilage. It travels superiorly to the right side of the angle of Louis before arching leftward.

The great vessels arise from the aortic arch behind the sternomanubrial joint. The brachiocephalic artery travels under the manubrium toward the right sternoclavicular joint. The left common carotid artery makes a similar

ascent under the manubrium but travels toward the left sternomanubrial joint before entering the neck. The left subclavian artery travels just left of the common carotid artery. The use of surface anatomy to guide incisions and approaches for various thoracic and cardiac procedures will be discussed in later chapters.

Transcribing a chest radiograph and a computed tomographic scan to a physical location on a patient is vital for any thoracic surgical procedure, but it is particularly important for video-assisted thoracic surgery (VATS). Often, small nodules are hard to palpate thoracoscopically unless a more localized area is identified. Anatomic landmarks can help to divide and further subdivide the lung to help localize these nodules (Fig. 1-10).

MEDIASTINUM

The mediastinum is centrally located in the thoracic cavity. A pleural cavity bounds each side of the mediastinum, and its inferior and superior borders are defined by the diaphragm and the thoracic inlet, respectively. In classic descriptions, the mediastinum is divided into a superior and inferior mediastinum. The superior mediastinum lies above the plane from the sternomanubrial joint to the fourth thoracic vertebra. In the superior compartment lies the upper part of the thymus, the lower ends of the strap muscles, and the upper half of the superior vena cava, trachea, thoracic duct, and esophagus. The inferior compartment is further subdivided into anterior, middle, and posterior.

In 2000, Shields recategorized the mediastinum into three compartments: anterior, middle, and posterior. The diaphragm and bilateral pleural cavities remain the inferior and lateral borders for each of these compartments. The superior border now extends to the thoracic inlet for each compartment. The anterior compartment lies

between the sternum and pericardium and the great vessels. The posterior compartment lies behind the pericardium, great vessels, and tracheal bifurcation and extends to the vertebral column. The middle mediastinum is between the anterior and posterior compartments and includes the entire thoracic inlet (Table 1-5). Disease entities of the mediastinum are discussed in later chapters.

FIGURE 1-10 ■ Algorithm for correlating a pulmonary nodule on a computed tomographic (CT) scan for the patient during the operation.

TABLE 1-5 Structures in the Mediastinum

Compartment	Structures or Tissues	Pathologic Entities
Anterior	Thymus Internal mammary artery Fat Internal thoracic and prevascular lymph nodes Connective tissue Ectopic parathyroid Substernal thyroid	Thymic disease Teratoma Substernal thyroid Disease of lymph nodes Parathyroid disease Bronchogenic cysts
Middle	Heart Great vessels Trachea Proximal bronchi Vagus and phrenic nerves Esophagus Thoracic duct Proximal azygos vein Descending aorta Paratracheal lymph nodes	Lymph node disease (malignant and benign) Esophageal disease Tracheal disease Bronchogenic, pericardial, and esophageal cysts Morgagni hernia Angiomas
Posterior	Sympathetic chain Distal azygos vein Posterior paraesophageal lymph nodes	Neurogenic tumors Spinal lesions

TRACHEOBRONCHIAL TREE

The trachea is a continuation of the larynx at the infra-cricoid level. Its average length is 11.8 cm. It has approximately 17 to 21 incomplete cartilaginous rings (4 mm wide and 1 mm thick) that maintain its elliptical shape in adults, but the shape is more circular in children. The coronal dimensions in men and women are 13 to 25 mm and 10 to 21 mm, respectively. The sagittal dimensions also differ between the sexes: 13 to 27 mm in men and 10 to 23 mm in women. With flexion of the neck, the trachea becomes almost completely an intrathoracic organ, coursing backward and downward from a subcutaneous position to rest ultimately on the esophagus and vertebral column at the level of the carina. Bearing a common embryologic origin with the esophagus, these two structures remain in intimate contact with one another, with the posterior muscular membranous wall of the trachea resting on the esophagus. The thyroid is anterior to the trachea in the neck and in the mediastinum, the thymus and parts of some of the great vessels lay anterior to the distal trachea.

The isthmus of the thyroid crosses the trachea at the second ring. The innominate artery crosses the mid trachea obliquely from right to left, and the arch of the aorta indents the esophagus slightly and appears to shift the trachea toward the right, away from its midline position. Lateral structures on the right side are predominantly venous and include the superior vena cava, azygos,

and right brachiocephalic veins; lateral arterial structures on the left side include the arch of the aorta and the left common carotid artery. Both right and left vagi, along with their recurrent laryngeal nerves and the right and left sympathetic trunks, are also laterally related to the trachea. These intimate relationships of the trachea with surrounding organs are of important concern when performing cervical mediastinoscopy with lymph node biopsy.

Segmental blood supply to the trachea is from the inferior thyroid, subclavian, supreme intercostals, internal thoracic, innominate, and superior and middle bronchial arteries. This blood supply is shared with the esophagus and the main bronchi. Anastomotic arcades develop on the lateral tracheal wall and feed transverse vessels that travel between cartilaginous rings. For this reason, the trachea should not be devascularized circumferentially for a distance greater than 1 to 2 cm. The lateral arcades allow safe pretracheal dissections. Lymph drains to the posterior inferior group of deep cervical nodes and to paratracheal nodes.

The trachea bifurcates into the right and left principal bronchi (Fig. 1-11). The right principal bronchus arises in a more direct line with the trachea at an angle of approximately 25 degrees and passes behind the superior vena cava to reach the hilum of the lung. The left principal bronchus is slightly smaller, leaves the trachea more obliquely at an angle of approximately 45 degrees, passes below the arch of the aorta and the left pulmonary artery, and is almost twice as long as the right main bronchus

FIGURE 1-11 ■ Bronchoscopic view of the tracheobronchial tree. See Figure 1-12 for names of the numbered segments.

(4 to 6 cm). The carinal angle can be wider in women and obese people. It can also be wider in patients with bulky subcarinal nodal disease.

The right upper lobe bronchus, also known as the *eparterial bronchus*, branches from the lateral wall of the right principal bronchus approximately 1.2 cm distal to the trachea. The upper lobe bronchus, approximately 1 cm in length, gives off three segmental bronchi as it makes almost a 90-degree angle with the right main bronchus and the bronchus intermedius. After a distance of approximately 1.5 to 2 cm, the middle lobe bronchus arises from the anterior surface of the bronchus intermedius. The middle lobe bronchus is 1.5 to 2.2 cm long and bifurcates into lateral and medial branches. The superior segmental bronchus to the lower lobe arises from the posterior wall of the bronchus intermedius as it terminates into the basal-stem bronchus that sends off segmental bronchi to the medial, anterior, lateral, and posterior basal segments. The medial basal segment arises antero-medially, whereas the lateral basal and posterior basal segments most often arise as a common stem.

The longer left principal bronchus bifurcates into the upper lobe bronchus that travels anterolaterally and the lower lobe bronchus that continues posteromedially. The left upper lobe bronchus divides into the superior and inferior divisions that supply the upper lobe and lingula, respectively. The superior division branches into an apical posterior segmental bronchus and an anterior segmental bronchus. The inferior or lingual bronchus, which is the equivalent of a middle lobe bronchus on the right, is 1 to 2 cm long and divides into the superior and inferior divisions. The lower lobe bronchus on the right side gives off the superior segmental bronchus as its first branch before the basal trunk continues for about 1.5 cm as a single trunk; this then bifurcates into an anteromedial basal segmental bronchus and a common bronchial stem for the remaining basal segments.

Anatomic variations usually involve segmental bronchi arising as a common stem. Occasionally, additional bronchi arise from the main stem and distribute to a segment that has its own bronchus. A right upper lobe bronchus originating from the trachea (a porcine tracheobronchial tree) occurs in 3% of the population. Recognizing aberrant tracheobronchial anatomy is important for placement of the double-lumen endotracheal tube and for performing the ensuing surgical procedure.

LUNGS

To conserve healthy tissue and to perform operations safely on the lung, the thoracic surgeon must have a thorough knowledge of the segmental bronchopulmonary anatomy. Developing as outpouchings of the foregut, the ventral lung buds undergo repeated branching to yield approximately 20 generations from the principal bronchi to the terminal alveolar sacs. With the bronchus at the center, each bronchopulmonary segment functions as an individual unit with its own pulmonary arterial and venous supply. Importantly, the pulmonary veins run in the intersegmental plane and do not accompany the bronchus and the pulmonary artery to each unit.

The lungs are free of the pleural cavity except for attachments to the heart, trachea, and inferior pulmonary ligaments. The larger right lung has three lobes—upper, middle, and lower—and is composed of 10 bronchopulmonary segments. The left lung has two lobes—upper and lower—and eight segments (Fig. 1-12). The lingula on the left side is the anatomic equivalent of the middle lobe and is incorporated into the upper lobe. The terminology proposed by Jackson and Huber for the pulmonary segments and the branches supplying them has been universally adopted. The apparent discrepancy of there being only eight segments on the left side is explained by the fact that the apical and posterior segmental bronchi of the left upper lobe and the anterior and medial segmental bronchi of the left lower lobe originate from a common stem bronchus (Fig. 1-13 and Table 1-6).

The oblique fissure on each side separates the lower lobe from the rest of the lung. Anomalous fissures of varying depth may be seen along any of the segments, but they are most commonly seen separating the superior

segment of the lower lobe. Rarely, the apical segment of the right upper lobe may be a true tracheal lobe, with its bronchus arising directly from the trachea. The azygos lobe is not a true segment, but is formed by the azygos vein cutting into the pleura and apex of the lung. Medlar evaluated 1200 lungs and found an incidence of incomplete oblique fissure on the left and right of 18% and 30%, respectively. Of these patients, 63% had an incomplete horizontal fissure.

The right and left hila have different characteristics (Table 1-7). The right hilum exits the mediastinum below the confluence of the azygos and superior vena cava, and behind the superior vena cava and right atrial juncture. The left hilum lies below the aortic arch. The position of the pulmonary artery is somewhat different on the two sides. On the left (Fig. 1-14), the artery lies anterior and superior to the bronchus and runs in a slightly posterior

TABLE 1-7 Characteristics of Left and Right Lung and Their Lobes

Side or Lobe	Characteristics
Right lung	Hilum enters behind the superior vena cava or the right atrial juncture below the azygos nerve Ten segments Three lobes with a horizontal and oblique fissure The most superior and posterior structure in the right hilum is the right main-stem bronchus The right pulmonary artery is superior and slightly posterior to the right superior pulmonary vein The right pulmonary artery is inferior and anterior to the right main-stem bronchus Pulmonary veins most often enter heart separately
Left lung	Hilum courses under aortic arch Eight segments Two lobes with an oblique fissure Left pulmonary artery lies anterior and superior to the left main-stem bronchus The left superior vein is anterior and inferior to the left pulmonary artery Greatest variation in number and location of pulmonary artery branches Superior and inferior veins form common trunk before entering left atrium in 25% of the population
Right upper lobe	Arterial supply from truncus anterior branch coming off right main pulmonary artery at apex of hilum and from posterior ascending artery, found posterior to superior pulmonary vein or in fissure as ongoing pulmonary artery exits lung parenchyma Venous drainage into upper division of superior pulmonary vein Right upper lobe bronchus posterior in hilum Three segments
Right middle lobe	Arterial supply from one (45%) or two (48%) middle lobe arteries found from the right pulmonary artery at the confluences of the horizontal and oblique fissures Middle lobe vein drains most often into superior pulmonary vein and occasionally into inferior pulmonary vein Middle lobe bronchus from bronchus intermedius Two segments
Right lower lobe	From anterior to posterior: middle lobe vein, bronchus, artery Superior segmental artery and basilar artery are terminal branches of right pulmonary artery in the fissure Inferior pulmonary vein Right lower lobe bronchus Five segments
Left upper lobe	From anterior to posterior: inferior pulmonary vein, pulmonary artery, bronchus Two to eight arterial branches First branch of the pulmonary artery comes off behind superior pulmonary vein Varying number of posterior ascending arteries are given off after first branch as the pulmonary artery courses over and behind the left main-stem bronchus Lingular artery: most anterior branch in fissure going to upper lobe Superior pulmonary vein with upper division and lingular veins Four segments
Left lower lobe	Left upper lobe bronchus posterior to vein Superior segmental artery and basilar artery are terminal branches of right pulmonary artery in the fissure Inferior pulmonary vein Left lower lobe bronchus Four segments
Segments	From anterior to posterior: inferior pulmonary vein, pulmonary artery, bronchus Triangular parenchyma with apex toward center Bronchus runs in middle of segment Segmental artery on posterior surface of bronchus Veins in intersegmental planes Veins vary more than arteries, which vary more than bronchus Lingular and superior segmentectomies are easiest Basilar and apical segmentectomies harder Anterior segmentectomy hardest

direction before curving around and behind the left upper lobe bronchus. The right main-stem bronchus is the most superior and posterior of the right hilar structures, and the artery, though slightly anterior, is inferior to the bronchus (Fig. 1-15). The superior pulmonary veins are inferior and anterior to the pulmonary arteries, and the inferior pulmonary veins are even more inferior and posterior to the superior veins.

The main pulmonary artery arises to the left of the aorta and passes superiorly and to the left, anterior to the

left main-stem bronchus, where it divides into the right and left main pulmonary arteries. The right pulmonary artery passes to the right behind the ascending aorta and forms the superior border of the transverse sinus. It then passes posterior to the superior vena cava and forms the superior border of the postcaval recess of Allison, whereas the right superior pulmonary vein forms the inferior border of the recess. The first branch is the truncus anterior (rarely intrapericardial); it arises superolaterally and supplies the upper lobe before the pulmonary artery

FIGURE 1-14 ■ The medial surface of the left lung.

FIGURE 1-15 ■ The medial surface of the right lung.

FIGURE 1-16 ■ Hilum of the right lung. **A**, Anterior view. **B**, Posterior view. *Br*, Branch; *PA*, pulmonary artery; *RLL*, right lower lobe; *RUL*, right upper lobe.

enters the lung hilum (Fig. 1-16). The interlobar pulmonary artery goes between the bronchus intermedius (posterior) and superior pulmonary vein (anteriorly) and gives off the posterior ascending artery to the posterior segment of the upper lobe (Fig. 1-17). The ongoing pulmonary artery then runs behind the middle lobe bronchus. Opposite the posterior ascending artery, the middle lobe artery arises anteromedially, usually at the junction of the horizontal and oblique fissures. The arterial branch to the superior segment of the lower lobe arises posteriorly and opposite the middle lobe artery at the same level or slightly distal to it. Beyond the superior segmental artery, the common basal trunk continues in the fissure to give rise to the medial basal segmental artery, occasionally as a common branch with the anterior basal branch. The terminal branches supply the lateral and posterior basal segments.

The left pulmonary artery passes more posteriorly and superiorly than the right and is longer before giving off its first branch. Commonly, there are four branches to the left upper lobe, but the number varies from two to seven. The first branch arises from the anterior portion of the artery and is quite short, and often its branches

FIGURE 1-17 ■ Pulmonary artery as it exits the parenchyma of the right upper lobe into the confluence of the major and minor fissures. *PA*, Pulmonary artery.

FIGURE 1-18 ■ Hilum of the left lung. **A**, Anterior view. **B**, Posterior view. BR, Branch; Lt., left; PA, pulmonary artery; PV, pulmonary vein.

appear as separate vessels arising from the main artery. The second branch usually arises posterosuperiorly as the main artery passes over the left upper lobe bronchus and into the interlobar fissure, where more ascending upper lobe branches may originate (Fig. 1-18). As it enters the interlobar fissure, it gives off a branch to the superior segment of the left lower lobe and the lingular artery. Beyond the lingular branch, the common basal trunk divides into two major branches. The anterior branch supplies the anteromedial basal segments and the posterior branch supplies the lateral basal segments.

Among the common variations of the pulmonary arterial supply, the first anterior trunk on the left may be the major supply to the lingular segments. This should be suspected if a small lingular artery is found in the anterior fissure. The right side may have two major arteries that arise from the truncus anterior, which are designated the truncus anterior superior and the truncus anterior inferior.

The left superior pulmonary vein receives all the tributaries from the left upper lobe. It is closely applied to the

anteroinferior portion of the pulmonary artery and makes dissection of the anterior branches quite hazardous. Its three main tributaries are apical posterior, anterior, and lingular. Occasionally, the superior and inferior lingular veins are separate. A common anomaly is drainage of the inferior lingular vein into the inferior pulmonary vein. The inferior pulmonary vein, lying more posteriorly and inferiorly, drains the entire lower lobe via two principal tributaries, the superior segmental and common basal veins. The right superior pulmonary vein is usually made up of four branches: the apical anterior, anterior-inferior, and posterior branches, which drain the upper lobe, and the inferior branch, which drains the middle lobe. Occasionally, the middle lobe vein drains into the atrium as a separate vessel and very rarely it becomes a tributary of the inferior pulmonary vein.

The right inferior pulmonary vein is similar to the one on the left and is composed of two trunks. The common basal vein is composed of the superior basal and inferior basal tributaries, and the superior segmental vein drains the superior segment of the lower lobe. The superior and

inferior pulmonary veins on the right most often enter the left atrium separately. In contrast, on the left, the two veins form a common trunk in more than 25% of the population.

The segmental branches of the pulmonary arteries usually lie on the superior or lateral surface of the segmental bronchus that they accompany and with which they branch. The venous tributaries occupy an intersegmental position, do not bear as close a relationship to the segmental bronchi, and tend to lie on their medial or inferior surfaces. Variations from the usual pattern are common. As a general rule, veins vary more than arteries, and arteries vary more than bronchi.

The systemic circulation of the lung tissues is derived from the bronchial arteries that supply the bronchi from the carina to their terminal bronchioles and that also nourish the connective tissue and visceral pleura. A single right bronchial artery usually branches from the third posterior intercostal artery, and two left bronchial arteries usually branch from the dorsal aorta, one near vertebra T5 and one inferior to the left principal bronchus. Although variations are known, most bronchial arteries arise from the anterolateral aspect of the aorta or its branches within 2 to 3 cm of the origin of the left subclavian artery and come to lie on the membranous portion of the principal bronchi. The bronchial arteries usually give off branches to the esophagus and then follow the bronchi into the lung, also giving off branches along the interalveolar connective tissue septae to the visceral pleura. There is a rich anastomosis with the pulmonary arterial supply, which is important after pulmonary transplantation.

The bronchial veins have a superficial system, with two bronchial veins on each side draining from the hilar region and visceral pleura into the azygos vein on the right and the accessory hemiazygos vein on the left. Most of the venous drainage from the deeper lung substance drains into the pulmonary venous system, accounting for the less than 100% saturation of the blood in the left atrium.

Lymphatic drainage channels run toward the hilum from subpleural vessels along the bronchi and pulmonary arteries. This flow is interrupted by multiple lymph nodes along the way, mostly situated at forking points of the bronchi. Each nodal station has a number assigned to it and is the basis of the most recent staging system for primary bronchogenic carcinoma, as proposed by [Moun-tain and Dressler in 1997](#).

The most peripheral pulmonary nodes include subsegmental lymph nodes (level 14) and segmental (level 13), lobar (level 12), and interlobar (level 11) nodes in the fissures, and they are reliably removed during a lobectomy. The hilar lymph nodes (level 10), also known as *bronchopulmonary nodes*, are at the root of the lung and can be accessed using thoracoscopy or thoracotomy. The inferior pulmonary ligament nodes (level 9) lie in the inferior pulmonary ligament on the left and the right, and the parasophageal nodes (level 8) lie dorsal to the posterior wall of the trachea and inferior to the carina, to the right or left of the midline esophagus ([Fig. 1-19](#)). From then onward, drainage is to the central mediastinal and tracheobronchial nodes and upward via mediastinal lymph trunks to the brachiocephalic veins (see [Fig. 1-19A](#)).

The right and left paratracheal lymph nodes (levels 2R and 2L), and the lower paratracheal lymph nodes at the tracheobronchial angle (levels 4R and 4L), and the subcarinal (level 7) lymph nodes can be identified and sampled via a standard cervical mediastinoscopy. During a right VATS or right thoracotomy, lymph nodes at levels 4R, 7, 8, and 9 can be sampled (see [Fig. 1-19C and E](#)). The Chamberlain procedure or the left VATS procedure can give access to the subaortic (level 5) and para-aortic (level 6) lymph nodes. Left VATS can also provide access to lymph nodes at levels 7, 8, and 9 (see [Fig. 1-19B and D](#)). The Delphian lymph node (the highest mediastinal, pretracheal lymph node) is classified as level 1.

Thus, levels 1 through 9 are considered mediastinal lymph nodes, and metastases are classified as N2 if ipsilateral and as N3 if contralateral spread of cancer is present in these lymph node stations. Anomalies of this ipsilateral, centrally directed drainage pattern are common and are more likely on the left side, especially with lower lobe tumors. Up to 50% of left lower lobe tumors and 35% of left upper lobe tumors have positive contralateral (N3) mediastinal nodes, whereas contralateral metastasis is found in only 42% of right lower lobe tumors and 18% of right upper lobe tumors when N2 lymph nodes are negative for tumor. Instead of draining to hilar nodes, the left upper lobe tumors follow an alternative path to the subaortic, periaortic, and anterior mediastinal nodes in up to one third of patients.

The vagus nerve and the sympathetic plexus contribute to the poorly developed anterior pulmonary plexus around the main pulmonary arteries, and to the well-developed posterior plexus of nerves around the bronchi. The vagus nerve carries all the afferent innervation from the bronchial mucosa, sensing stretch in the alveoli and pleura, pressure in the pulmonary veins, and mediating pain. Efferent fibers in the vagus constrict the bronchi, and the sympathetic efferents are vasoconstricting to the pulmonary vessels and secretomotor to the bronchial plexus.

The left and right hemithoraces each contain a variety of other vital organs in addition to the lungs. The thoracic duct, esophagus, aorta, and azygos vein can be visualized in the right hemithorax, whereas the aortic arch, descending aorta, and distal esophagus may be seen in the left hemithorax.

ESOPHAGUS

The esophagus is a muscular tube that starts at the upper esophageal sphincter (the cricopharyngeus) and travels approximately 25 cm to the lower esophageal sphincter at the gastroesophageal junction. The cricopharyngeus is 15 cm from the incisor teeth. With endoscopy, the gastroesophageal junction is measured to be 38 to 40 cm from the incisors in men, and generally 2 cm shorter in women. The cervical esophagus is slightly left of midline as it enters the thoracic inlet in front of the body of the T1 vertebra and posterior to the trachea. After it passes the aortic arch, it inclines forward and passes in front of the descending thoracic aorta to obtain a position left of midline as it travels through the esophageal hiatus

FIGURE 1-19 ■ Mediastinal lymph nodes. **A**, Anterior view. **B**, Left lung retracted posteriorly to expose lymph nodes at levels 5, 6, and 9. **C**, Anterior retraction of the left lung to expose lymph nodes at level 7. **D**, Anterior retraction of right lung to expose lymph nodes at levels 7, 8, and 9. **E**, Inferior and posterior retraction of right lung to expose lymph nodes at level 4R. SVC, Superior vena cava.

opposite the body of the 10th thoracic vertebra. At the level of the T8 vertebra, the left lateral wall of the esophagus that was covered by the aorta is in contact with the parietal pleura as the aorta goes directly behind it. This is a common site of perforation in patients with Boerhaave syndrome. The right lateral surface of the esophagus is completely covered by parietal pleura except where the azygos vein crosses it at the level of the T4 vertebra. When choosing the side for a thoracotomy, avoiding interference from the aortic arch is the primary concern. Access to the proximal esophagus is difficult from the left hemithorax because of the overlying aortic arch.

Endoscopic examination of the esophagus reveals several constrictions on the esophageal lumen in addition to the narrowing at the upper and lower esophageal sphincters. The additional constrictions are seen endoscopically where the esophagus crosses the aortic arch at 22 to 25 cm from the incisors, and where it is crossed by the left main-stem bronchi at 27.5 cm from the incisors. These anatomic relationships may also be seen radiographically. A notch indentation is often seen in its left lateral wall on a barium swallow radiograph as the esophagus passes to the right of the aorta at the level of the tracheal bifurcation. The left main-stem bronchus may indent it slightly as it passes over the esophagus.

The blood supply of the cervical esophagus is from branches of the inferior thyroid artery. The thoracic esophagus is supplied by the esophageal branches of the aorta and the bronchial arteries. Most individuals have one right-sided and one or two left-sided bronchial arterial branches. The upper aortic esophageal branch is usually shorter and originates at the T6 or T7 vertebral level, and the lower larger branch originates at the level of the eighth or ninth thoracic vertebra. Finally, the abdominal esophagus receives its supply from branches of the left gastric and inferior phrenic arteries. In the wall of the esophagus, there is an extensive longitudinal anastomotic network in the muscular and submucosal layers, a basis for portasystemic anastomoses. The venous drainage follows the arterial supply. A submucosal plexus drains into a periesophageal venous plexus, from which the veins originate and empty into the inferior thyroid, bronchial, azygos, and left gastric veins.

Two large interconnecting networks that course longitudinally form the lymphatic network of the esophagus. The mucosal network extends into the submucosal network, and flow is predominantly (6:1) longitudinal rather than segmental. These pierce the muscular wall, and ultimately lymph channels follow the arterial supply. The cervical esophagus drains into the deep cervical nodes alongside the inferior thyroid vessels, whereas the abdominal portion drains to the preaortic group of the celiac nodes along the left gastric artery. The thoracic esophagus drains into the tracheobronchial nodes superiorly and the subcarinal and paraesophageal nodes inferiorly.

After giving off their recurrent laryngeal branches, which supply the cricopharyngeal sphincter and cervical esophagus, the vagus nerves descend onto the anterior wall of the esophagus and form a complex vagal esophageal plexus, a network of interconnecting fibers that forms the preganglionic parasympathetic supply to the esophagus. These fibers connect to the enteric ganglia in

the myenteric and submucosal plexuses that are located in the wall of the esophagus. Just above the diaphragm, the plexus usually gives rise to two nerve trunks: the anterior and posterior vagal. The anterior trunk contains predominantly left vagal fibers and the posterior contains mainly right, with considerable contribution from one another.

Cervical and thoracic sympathetic ganglia contribute visceral branches to the esophagus, and a few branches from the splanchnic nerves reach the esophagus. Their effect on the esophageal muscle is unknown. The vagus nerve is the motor supply to the esophageal muscle, and the secretomotor nerve supplies the esophageal glands. Afferent pain fibers appear to run in both the vagal and vasomotor sympathetic supply; hence, esophageal pain can be referred to the neck, arm, and thoracic wall.

The mucosal lining of the esophagus is composed of nonkeratinized, stratified squamous epithelium supported by a lamina propria and a thick muscularis mucosa. The mucous membrane is thick and in the collapsed state is thrown into longitudinal folds. Mucosal glands in the submucosa are mainly found at the upper and lower ends of the esophagus. The muscular wall consists of an inner circular and an outer longitudinal layer that are visceral smooth muscle in the lower two thirds and skeletal striated muscle in the upper third. Except for the short intra-abdominal segment, the lack of a serosa in the rest of the esophagus accounts for the difficulty in suturing the esophagus.

VESSELS OF THE THORAX

Descending Thoracic Aorta

The descending thoracic aorta starts at the level of the fourth thoracic vertebra. It is a posterior mediastinal structure that arises just left of the vertebral column and travels toward the midline as it descends toward the diaphragm. When it goes through the aortic hiatus at the level of the 12th thoracic vertebra, it is anterior to the vertebral column. In the left hemithorax, anterior to the descending aorta, are the left pulmonary hilum, the pericardium, and the esophagus, and posteriorly is the vertebral column. In the right hemithorax, the esophagus is lateral to the aorta until it takes up a position anterior to the aorta near the diaphragm. The thoracic duct and azygos vein are lateral to the aorta in the right hemithorax. Branches of the descending thoracic aorta include pericardial, bronchial, mediastinal, phrenic, and posterior intercostal and subcostal arteries. The descending aorta is fixed at the origin of the left subclavian artery, which is therefore a common site for transection of the aorta during motor vehicle accidents.

Azygos Vein

The origin of the azygos vein is not constant. It typically starts from the posterior aspect of the inferior vena cava, but it may originate from a lumbar azygos vein or from the confluence of the subcostal and ascending lumbar vein. It ascends through the aortic hiatus in the

diaphragm. It rises in the right hemithorax in the posterior mediastinum until the fourth vertebral body, and then it turns medially over the right pulmonary hilum to join the superior vena cava.

Thoracic Duct

The thoracic duct carries chylous material, which is rich in lipids, proteins, and lymphocytes. It begins at the confluence of the abdominal lymphatic trunks known as the cisterna chyl. From its origin at the level of the 12th thoracic vertebra, the thoracic duct travels through the aortic hiatus and ascends in the right hemithorax between the descending thoracic aorta (medial) and the azygos vein (lateral) and posterior to the esophagus, until it crosses medially at the level of the fifth thoracic vertebral body. Once in the left hemithorax, it continues its ascent on the left side of the esophagus. It crosses the aortic arch anteriorly and then travels posterior to the left subclavian artery. It travels out of the thoracic inlet for 3 to 4 cm before arching and descending anterior to the medial border of the scalenus anterior and finally joining the venous system near the confluence of the left subclavian and internal jugular veins.

NERVES OF THE THORAX

Vagus and Recurrent Laryngeal Nerves

The vagus nerve passes inferiorly from the base of the skull to the thoracic inlet in the carotid sheath. On the right side, the right vagus travels behind the internal jugular vein and dives behind the sternoclavicular joint to give off the right recurrent laryngeal nerve. The right recurrent laryngeal nerve recurs on the ipsilateral subclavian artery and then ascends in the tracheoesophageal groove. The left recurrent laryngeal nerve recurs on the aortic arch and then rises in the tracheoesophageal groove. Both recurrent laryngeal nerves enter the larynx with the laryngeal branch of the inferior thyroid artery.

The right vagus continues to descend into the thoracic cavity behind the right brachiocephalic vein and then lateral to the trachea. It travels posteriorly and lies predominantly posterior to the right pulmonary hilum, where several bronchial branches are given off. The remaining vagal fibers join fibers from the left to form the posterior vagal trunk.

The left vagus enters the thorax between the common carotid and the subclavian arteries behind the left brachiocephalic vein. It crosses the left side of the aortic arch and gives off the left recurrent laryngeal nerve before descending behind the left pulmonary hilum. It also gives off bronchial branches at this level. Fibers from the left and right vagi form the anterior and posterior vagal trunks, which enter the abdomen through the esophageal hiatus.

Thoracic Sympathetic Chain

The thoracic sympathetic chain is formed by ganglia of the autonomic nervous system. The first thoracic

ganglia, in the majority of patients, fuses with the inferior cervical ganglia. The thoracic sympathetic chain predominantly lies on the costal head under the pleura. The nerves interact with corresponding spinal nerves with white and gray rami. Ligation of sympathetic ganglia is performed to treat hyperhidrosis, facial blushing, Raynaud disease, and reflex sympathetic dystrophy. When collateral nerve fibers bypass the sympathetic trunk, sympathectomy results in failure. These fibers can reach the brachial plexus without passing through the sympathetic ganglia. The nerve of Kuntz is the most described collateral nerve. Although in clinical literature, the nerve of Kuntz is reported in 10% of cases, it is reported 80% of the time in anatomic descriptions. Techniques for ligation of ganglia from T1 to T3 are discussed in later chapters.

Phrenic Nerves

The right and left phrenic nerves arise from the third, fourth, and fifth cervical rami and course inferiorly in an oblique manner on the respective anterior surfaces of the scalenus anterior muscle. At the thoracic inlet, the nerve is on the medial border of the scalenus anterior muscle, just 3 to 4 cm from the sternoclavicular joint. It then enters the thoracic inlet posterior to the subclavian vein and anterior to the internal mammary artery. Injury to the phrenic nerve may occur during surgical procedures such as a scalene node biopsy or Pancoast tumor resection. When dissecting a pre-scalene node, which is often done for lung cancer staging or confirmation of sarcoidosis, caution should be used to avoid entering the scalenus anterior sheath in which the phrenic nerve lies. Pancoast tumor resections require division of the first rib. The scalenus anterior muscle should be divided as close to the first rib as possible to avoid injury to the overlying phrenic nerve.

After entering the thoracic cavity, the right phrenic nerve travels inferiorly, just lateral to the brachiocephalic vein and the superior vena cava. It continues its descent over the pericardium and the underlying right atrium and inferior vena cava. Just as it goes through the diaphragm, it divides into three branches: the anterior, posterior, and anterolateral.

The left phrenic nerve at the root of the neck may pass anterior to the first part of the subclavian artery and behind the thoracic duct, or it may follow the same course as the right phrenic nerve. It then crosses anterior to the internal mammary artery and travels in the groove between the left common carotid and subclavian arteries. The nerve crosses anteromedial to the aortic arch and travels over the pericardium toward the diaphragm. In the same manner as its right-sided counterpart, the nerve divides as it travels through the diaphragm to give off branches on the abdominal surface. The branches travel from its central position in the diaphragm to supply the sternal, crural, and posterior aspects of the diaphragm. Radial incisions in the diaphragm from the costal edge to the esophagus will lead to damage of the phrenic nerve. Peripheral circumferential incisions in the diaphragm are safest with regard to the phrenic nerve. Similar incisions in the central tendon are also safe.

SUMMARY

Since the late 1990s advances in imaging technology, including digital subtraction chest radiographs, multi-detector spiral computed tomography (MDCT), dual-energy computed tomography (CT) techniques, electrocardiograph (ECG)-gated CT, positron emission tomography (PET) with CT, and magnetic resonance imaging (MRI), have improved diagnostic accuracy and management of patients with thoracic abnormalities. The electronic distribution of these studies as digital images via a picture archiving and communication system, has also expedited information transfer and interpretation.

This chapter is a general overview of the advances in thoracic imaging, with a focus on imaging modalities used for the evaluation of the surgical patient. Topics reviewed include a spectrum of mediastinal, lung, pleural, and chest wall abnormalities commonly encountered by thoracic surgeons in which imaging is important in the diagnosis and management of patients.

MEDIASTINAL ABNORMALITIES

Mediastinal abnormalities have a variety of causes, including congenital malformations, infections, trauma, and neoplasms. Clinical history and prior radiographs are often sufficient to determine the cause and the necessity for further evaluation. In the absence of prior imaging studies, chest radiographs, CT, or MRI are most commonly used to establish a diagnosis or to provide a differential diagnosis.

Aorta

Multidetector computed tomography, dual-energy CT, and ECG-gated CT together with sophisticated post-processing methods have transformed imaging of the thoracic aorta. More recently, rapidly acquired (single breath-hold) non-ECG-gated CT imaging has become available and is being used as the initial diagnostic imaging modality to evaluate patients with suspected acute aortic dissection. Furthermore, because single-acquisition dual-source CT with the availability of low- and high-kVp data acquired from the same volume eliminates aortic precontrast imaging, reduces radiation exposure, and uniquely characterizes aortic pathology, it is being recommended in the initial evaluation of the aorta.

Aortic Dissection

Acute aortic syndrome is the term currently used to refer to a group of potentially life-threatening disorders of the thoracic aorta including aortic dissection, intramural hematoma (IMH), and penetrating atheromatous ulcer (PAU).¹ The most common presenting complaint in patients with acute aortic syndrome is acute onset of severe chest pain, but symptoms can be nonspecific and variable.^{1,2} Aortic dissection is the most common acute aortic disorder, and IMH and PAU account for 10% to 20% of acute aortic syndrome cases.^{2,3} Two different mechanisms leading to the characteristic intimal tear in aortic dissection have been proposed and remain

FIGURE 2-1 ■ Type B aortic dissection. **A**, Axial contrast-enhanced chest computed tomography shows a dilated descending aorta and an intimal flap (*arrows*). There are small pleural effusions and increased attenuation of mediastinal adipose tissue raising the possibility of hemorrhage within the mediastinum. **B**, Sagittal oblique magnetic resonance imaging of the aorta shows an intimal flap (*arrowheads*) arising distal to the left subclavian artery (*arrow*).

debatable: primary disruption of the intima versus secondary rupture of a hematoma arising from the vasa vasorum.^{4,5}

MDCT with intravenous contrast is the imaging modality of choice when an aortic dissection is suspected, and it can determine the type and extent of the dissection for management decisions. The DeBakey and Stanford classifications are widely recognized and both based on the origin of the intimal tear and the extent of the aortic involvement. Stanford Type A dissection involves the ascending aorta and originates just above the aortic valve plane; it is usually considered for surgical repair. Stanford Type B dissection originates just below the level of the ligamentum arteriosum, and it is generally managed medically. Endovascular or surgical interventions are indicated for patients who develop complications from Stanford Type B dissections (Fig. 2-1).

The primary diagnostic finding on CT is an intimal flap separating the true from the false lumen. The sensitivity and specificity approaches 100%, with an accuracy that is superior to that of angiography.⁶⁻⁸ Images are usually viewed as two-dimensional orthogonal axial sections, combined with volume-rendering and multiplanar reconstruction images. However, these techniques are unable to depict the dissection wall as a whole. To overcome this limitation, an automatic segmentation and three-dimensional visualization of the dissection wall has been proposed to isolate the dissection (or flap) from the rest of the vascular structures and improve diagnosis and characterization of the dissection.⁹ When iodinated contrast agents are contraindicated, MRI or transesophageal echocardiography can be used to diagnose and determine the type of dissection.¹⁰ Although these imaging modalities are accurate, both have limitations in large patients, and the ability to perform these studies in the acute setting is not optimal.

Aortic Trauma

Patients with thoracic trauma usually require imaging evaluation, and the type of study depends on the mechanism of injury and the structures potentially involved. From an imaging perspective, the chest radiograph is typically the first study performed and often dictates whether additional imaging is warranted. The radio-

FIGURE 2-2 ■ Traumatic aortic injury. Portable chest radiograph shows widening of the superior mediastinum, lobular contour abnormality of the transverse aorta (*arrow*), indistinct descending aorta, and opacities in the left lung consistent with pulmonary contusion/hemorrhage.

graphic findings suggestive of traumatic aortic injury (TAI) are an indistinct aortic arch or descending aorta, a left apical cap, tracheal displacement to the right, displacement of the nasogastric tube to the right of the T4 spinous process, mediastinal widening, and inferior displacement of the left main-stem bronchus (Fig. 2-2).¹¹⁻¹³ Less specific findings include a left pleural effusion and widening of the paravertebral stripe. These features, however, are only suggestive, not indicative, of an aortic injury. In contrast, the negative predictive value of a normal chest radiograph for an aortic injury is 94% to 96%.^{14,15} If there is a chest radiographic abnormality, MDCT is the primary imaging method for the diagnosis of TAI. The sensitivity for this technique is 100%, and the specificity ranges from 83% to 99.7% (Fig. 2-3).¹⁶⁻²⁰ In fact, MDCT has superseded aortography in the

FIGURE 2-3 ■ Traumatic aortic injury after motor vehicle accident. **A**, Axial contrast-enhanced chest computed tomography (CT) shows focal contained collection of contrast (*asterisks*) located external to the descending aorta, consistent with a pseudoaneurysm. Note mediastinal widening due to hemorrhage and moderate pleural effusion. **B**, Sagittal reconstructed CT shows pseudoaneurysm arising from the thoracic aorta immediately distal to the transverse arch (*asterisk*). (Courtesy Page H. McAdams, Duke University, Durham, N.C.)

diagnosis of TAI and vascular injuries and selective aortography is now reserved for therapeutic catheter-based endovascular interventions. Direct signs for TAI include a linear intraluminal filling defect, pseudoaneurysm formation, an abrupt caliber change, and contrast extravasation. Indirect signs of TAI, most notably a periaortic hematoma, are found in 91% of patients with surgically proven TAI.¹⁷ The absence of a periaortic abnormality and a normal-appearing aorta on MDCT has a negative predictive value of 100%.^{19,20} Additional nonvascular thoracic injuries can be found in 7% of patients who do not have an aortic transection on MDCT. Such abnormalities are usually a combination of pneumothoraces, multiple rib fractures, and pulmonary contusions.^{17,21}

Trauma: Airways and Esophagus

Tracheal and esophageal injuries are uncommon but are typically found after intubation, a motor vehicle crash, or penetrating trauma (Fig. 2-4). Many of these injuries are not recognized initially because of subtle or nonspecific clinical and radiologic findings. Delayed or missed

FIGURE 2-4 ■ Tracheal rupture after a motor vehicle crash in a patient with no respiratory symptoms and a chest radiograph demonstrating pneumomediastinum. Coronal reformations of computed tomography (2.5-mm collimation) show pneumomediastinum and discontinuation of the trachea (*arrows*).

diagnosis can result in death or severe complications, such as ventilatory failure, mediastinitis, sepsis, airway stenosis, bronchiectasis, recurrent pulmonary infections, and permanent pulmonary function impairment.

Injuries to the trachea or bronchi can be difficult to diagnose, because patients can have no clinical findings and the radiograph can be normal in up to 10%.^{22,23} In addition, the radiographic findings of tracheobronchial and esophageal injury are nonspecific and can include pneumomediastinum, pneumothorax, and progressive subcutaneous emphysema. However, diagnosis of these injuries is important because there is a high association with esophageal and major vascular injuries.^{22,23} MDCT with multiplanar reconstructions is the imaging modality of choice for visualization of the airways. MDCT has a sensitivity of 85% for the detection of tracheal injuries.^{22,23} Patients with tracheal rupture characteristically have an abnormal air collection in the thorax, and air can occasionally be demonstrated in the soft tissues of the neck.²² Success in visualizing the tracheal injury ranges from 71% to 94%, and multiplanar reconstructions can be useful in localizing and defining the extent of injury.^{22,24} MDCT also provides information about the esophagus, although if pneumomediastinum, with or without mediastinal fluid is present on chest radiographs or CT after trauma, fluoroscopic esophagography or endoscopy is usually warranted to exclude an esophageal tear. However, recently it has been reported that the high sensitivity and negative predictive value of CT in patients with pneumomediastinum being evaluated for esophageal perforation after trauma negates performing fluoroscopic esophagography.²⁵

Evaluation of Airways: Nontrauma

Focal or diffuse lesions of the central airways are produced by a variety of diseases, including infection, malignancy, trauma, aspiration, collagen vascular disease, and idiopathic entities such as sarcoidosis or amyloidosis. Although patients might have significant symptoms, airway abnormalities are frequently not apparent or are overlooked on the chest radiograph. If there is a clinical suspicion of a tracheobronchial abnormality, further evaluation by CT is warranted. MDCT using thin slices (1 to 3 mm) is preferred, as it produces excellent axial and multiplanar images, including virtual bronchoscopy, that allow complex tracheobronchial anatomy to be visualized, depicting even weblike stenosis that can easily be missed or underestimated with thicker sections (Fig. 2-5).²⁶ MDCT performed during dynamic exhalation is also useful in demonstrating the excessive tracheal collapse that can occur because of either weakness of the supporting tracheal cartilaginous structures (tracheomalacia) or from excessive anterior bulging of the posterior membranous wall of the trachea (excessive dynamic airway collapse).^{27,28} These related disorders are a potentially underdiagnosed cause of chronic respiratory symptoms.

Mediastinal Tumors

Mediastinal tumors, a large, diverse group of neoplasms, have historically been described radiographically according to their location in the anterior, middle, or posterior

compartments. This description facilitates differential diagnosis and can aid in treatment planning.

Tumors that occur primarily in the anterior mediastinum include hemangiomas, lymphatic malformations, thymic lesions (e.g., cysts, thymolipoma, thymoma, thymic carcinoma), parathyroid adenomas, germ cell tumors, and lymphoma (Fig. 2-6). CT and MRI are particularly useful for showing local soft tissue and vascular invasion of thymomas, local invasion, and early dissemination to regional lymph nodes of thymic carcinomas and, because of the varying composition of soft tissue, fat, calcium, and hemorrhage in teratomas, can occasionally differentiate these tumors from thymomas and lymphomas.

Tumors that occur primarily in the middle mediastinum are foregut malformations, pericardial cysts, and neoplasms arising from the esophagus and trachea. Bronchogenic cysts are the most common mediastinal foregut cysts and are typically located in the subcarinal or right paratracheal region. They appear on CT as round or spherical masses of water attenuation, although many have increased attenuation from proteinaceous debris or blood.²⁹ Esophageal tumors can manifest as middle mediastinal masses, although esophageal carcinoma more frequently manifests as diffuse thickening of the esophagus. Endoscopy and endoscopic-directed ultrasound biopsy are usually used to evaluate locoregional extent and nodal metastases. CT is useful in showing the extent of involvement of adjacent structures such as the airways, aorta, pericardium, and spine, and in revealing nodal (e.g., celiac, gastrophatic ligament) and systemic metastases.

FIGURE 2-5 ■ Focal stenosis of the right main-stem bronchus from invasive aspergillosis. **A**, Axial computed tomography shows normal caliber of left main bronchus and marked concentric narrowing of right main bronchus. **B**, Coronal reconstruction shows that the right main bronchus stenosis involves a short focal segment (arrow). A, Ascending aorta; P, pulmonary artery.

FIGURE 2-6 ■ Anterior mediastinal mass. **A**, Posteroanterior chest radiograph demonstrates a smoothly margined, left-sided anterior mediastinal mass. **B**, Axial computed tomographic image confirms the mass, with mixed heterogeneous components, including fat, soft tissue, fluid, and calcification. These findings are diagnostic of a teratoma.

Tumors that occur primarily in the posterior compartment are neurogenic tumors. In fact, 20% of all adult and 35% of all pediatric mediastinal neoplasms are neurogenic tumors, and most are located in the posterior mediastinum.³⁰ Neurogenic tumors are classified as tumors of peripheral nerves (neurofibromas, schwannomas, malignant tumors of nerve sheath origin) or sympathetic ganglia (ganglioneuromas, ganglioneuroblastomas, neuroblastomas) and are optimally assessed by MRI. MRI is the preferred modality for evaluating neurogenic tumors, because it can simultaneously assess intraspinal extension, spinal cord abnormalities, longitudinal extent of tumor, and extradural extension.

LUNG ABNORMALITIES

Thoracic imaging is essential in the workup of pulmonary abnormalities, including lung nodules and focal opacities,

intrathoracic malignancies, diffuse interstitial lung disease, and infection. Low-dose CT (LDCT) is being used as a screening tool for lung cancer and the National Lung Screening Trial, a randomized study comparing the effectiveness of LDCT to chest radiography in more than 50,000 participants, has reported significant reductions in lung cancer (20%) and all-cause mortality (6.7%).³¹

Solitary Pulmonary Opacities

Solitary pulmonary opacities are a common radiologic finding and are usually benign, but because of concern about lung cancer, further evaluation is often suggested. The goal is to differentiate malignant and benign lesions so that patients who require surgery are identified correctly. Although morphologic features can suggest whether a nodule is benign or malignant, there is considerable overlap, and at least 20% of malignant nodules have a benign appearance.^{32,33} Specific patterns of calcification and stability in size for 2 years have historically been the only reliable findings useful in determining benignity. More recently, the ability to distinguish between benign and malignant opacities has improved with the assessment of perfusion using contrast-enhanced CT and the assessment of metabolism using PET imaging with fluorodeoxyglucose labeled with radioactive fluoride (¹⁸F; FDG).

Contrast-enhanced CT can be used to differentiate benign and malignant nodules because the intensity of enhancement is directly related to the vascularity of the nodule and to the likelihood of malignancy.^{34,35} Typically, malignant nodules enhance greater than 20 Hounsfield units (HU), whereas benign nodules enhance less than 15 HU.³⁶ Although nodule-enhancement CT has a high negative predictive value, it is performed infrequently because of the general availability of FDG PET-CT.³⁷

FDG PET allows differentiation of malignant and benign nodules that are indeterminate after conventional imaging (Fig. 2-7). A metaanalysis of 40 studies on the accuracy of FDG-PET reports a sensitivity of 97% and a specificity of 78% when used in the evaluation of 10-mm or larger nodules.³⁸ However, a recent prospective integrated PET-CT evaluation of 585 patients (496 malignant, 89 benign nodules) showed that although a high standardized uptake value (SUV > 4.1) was associated with a 96% likelihood of malignancy, the likelihood of malignancy was still 25% when the SUV was 0 to 2.5.³⁹ Furthermore, in malignant nodules that are smaller than 1 cm in diameter or have ground-glass or partially solid morphology, FDG uptake is variable and unreliable in differentiating benign from malignant nodular opacities (Fig. 2-8).⁴⁰

Staging Lung Cancer

Staging—the assessment of the anatomic extent of non-small cell lung cancer (NSCLC)—usually determines treatment and prognosis. Clinical staging typically includes CT and, more recently, PET-CT. CT is typically used to determine the size, location, and presence of locoregional invasion of the primary tumor (T), the presence and location of nodal (N) metastasis, and intrathoracic and distant systemic metastasis (M1a, M1b).^{41,42}

FIGURE 2-7 ■ Non-small-cell lung cancer. **A**, Axial computed tomography shows a lobular left upper lobe nodule. **B**, Fused coronal positron emission tomography–computed tomography shows small nodule in the upper lobe with increased uptake of [^{18}F] fluorodeoxyglucose, consistent with malignancy. Note the absence of nodal and distant metastases.

FIGURE 2-8 ■ Non-small-cell lung cancer. **A**, Axial computed tomography shows a ground glass right upper lobe lung nodule (arrows). **B**, Whole body maximum intensity PET shows no uptake of [^{18}F] fluorodeoxyglucose (FDG) in the nodule. Note that FDG uptake is variable and unreliable in nodules with ground glass morphology and is not useful in differentiating benign from malignant nodules.

CT is also usually used to define chest wall or mediastinal invasion but is inaccurate in differentiating between anatomic contiguity and subtle invasion. MRI has better soft-tissue contrast resolution than CT and is useful in the evaluation of superior sulcus tumors and the brachial plexus (Fig. 2-9).^{43,44}

The presence of nodal metastases and their locations are important for determining management and prognosis (Fig. 2-10).^{41,42} CT is most commonly used to assess the size of nodes, and a short-axis diameter greater than

1.0 cm is the criterion typically used to diagnose nodal metastases. However, a limitation is the overlap in the size of malignant and benign lymph nodes. In this regard, a metaanalysis (20 studies, 3438 patients) evaluating CT for staging of the mediastinum yielded a pooled sensitivity of 57% and specificity of 82%.⁴⁵ PET imaging improves the accuracy of nodal staging. In a metaanalysis of 17 studies comprising 833 patients, the overall sensitivity of PET for detecting nodal metastases was 83% and the specificity was 92%, whereas the sensitivity

FIGURE 2-9 ■ Non-small-cell lung cancer superior sulcus tumor. **A**, Posteroanterior chest radiograph shows a right upper lobe mass (asterisk). **B**, Sagittal magnetic resonance imaging shows a mass invading the second and third ribs (arrows). Preservation of adjacent soft tissue planes (arrowheads) adjacent to the first rib (*R*) indicates that the C8 nerve root of the brachial plexus located superior to the rib is not involved by tumor and the patient is potentially a surgical candidate.

and specificity of chest CT were 59% and 78%, respectively.⁴⁶ Interestingly, in the presence of enlarged lymph nodes, PET and PET-CT become less specific and less accurate, but more sensitive in detecting nodal metastases.^{47,48}

The adrenal glands, liver, brain, bones, and lymph nodes are the most common sites of metastatic disease at presentation. However, the role of imaging these areas at presentation is not clearly defined. Routine imaging of the upper abdomen is performed as part of the initial chest CT evaluation in most patients with NSCLC.

FIGURE 2-10 ■ Non-small-cell lung cancer. **A**, Axial computed tomography shows left upper lobe lung malignancy (*M*) and enlarged right paratracheal node (arrow). **B**, Axial fused positron emission tomography–computed tomography shows increased uptake of [¹⁸F] fluorodeoxyglucose within the mass and right paratracheal lymph node consistent with a malignancy. Biopsy confirmed N3 nodal metastasis.

However, because clinical staging of NSCLC with CT and MRI is often inaccurate, whole-body imaging with PET-CT can be performed to improve accuracy. PET has a higher sensitivity and specificity than CT does in detecting metastases to the adrenal glands, bones, and extrathoracic lymph nodes. Whole-body PET imaging stages intrathoracic and extrathoracic disease in a single study, detects occult extrathoracic metastases in up to 24% of patients selected for curative resection, and is cost effective (Fig. 2-11).⁴⁹⁻⁵³

Metastases to the adrenal glands are detected in up to 20% of patients with NSCLC at presentation. If an adrenal mass contains fat or has an attenuation value of less than 10 HU on a noncontrast CT scan, the mass can be considered benign.⁵⁴ Lesions with attenuation values of greater than 10 HU can be further evaluated with MRI using chemical shift analysis and dynamic gadolinium enhancement to determine whether they are malignant or benign.⁵⁴ FDG-PET has a specificity of 80% to 90%;

FIGURE 2-11 ■ Non-small-cell lung cancer. Fused coronal positron emission tomography–computed tomography shows left upper lobe lung nodule (*asterisk*) with increased [^{18}F] fluorodeoxyglucose (FDG). Note focal increased FDG uptake in thoracic spine and pelvis due to metastases (*arrows*).

it is useful in distinguishing benign from malignant adrenal masses detected on CT and is particularly advocated when the adrenal mass is small.⁵⁵⁻⁵⁷

Routine CT or MRI of the central nervous system has been advocated because up to 18% of patients with NSCLC have brain metastases at presentation, and 10% of these patients have no associated neurologic symptoms. However, routine CT or MRI of the central nervous system remains controversial, as the yield is low for asymptomatic patients with early disease. The prevailing clinical practice is to perform CT or MRI for patients who have neurologic signs or symptoms, as well as for asymptomatic patients with stage III disease who are being considered for aggressive local therapy such as thoracotomy or radiation.^{58,59}

PET-CT has high specificity, sensitivity, negative predictive value, positive predictive value, and accuracy in the assessment of bone metastases. PET-CT has to a large extent replaced $^{99\text{mTc}}$ -labeled methylene diphosphonate bone scintigraphy in the evaluation of bone metastases in patients with NSCLC.^{60,61} Because routine imaging rarely reveals occult skeletal metastases in an asymptomatic patient, MRI is generally performed only if the patient has focal bone pain or an elevated alkaline phosphatase level.

Interstitial Lung Disease and Pulmonary Abscesses

Imaging studies are essential for determining the diagnosis in patients with pulmonary symptoms and focal or diffuse lung disease. If the diagnosis is uncertain after clinical and imaging evaluations, surgical biopsies can be requested before therapy is initiated. Radiologic studies are often useful in determining the optimal site to biopsy,

FIGURE 2-12 ■ Usual interstitial pneumonitis (UIP). Axial high-resolution computed tomographic image through the bases demonstrates diffuse lung disease with area of predominantly peripheral ground-glass opacities, architectural distortion, and cystic spaces consistent with pulmonary fibrosis. Lung biopsy confirmed UIP.

as well as the biopsy method (i.e., transbronchial or wedge biopsy; Fig. 2-12). Lung abscesses, usually caused by aspiration of anaerobic bacteria, typically occur in patients with altered levels of consciousness, gastroesophageal dysmotility, and poor dental hygiene. Medical therapy (systemic antibiotics, postural drainage) is the initial treatment of choice and is curative in most patients. However, lung abscesses in children younger than 7 years typically do not drain spontaneously and are less likely to respond to medical management. Surgical or percutaneous drainage is required in the 11% to 21% of patients with lung abscesses who fail to respond to medical therapy. Drainage of an abscess is recommended when (1) the patient has persistent sepsis 5 to 7 days after initiation of antibiotic therapy, (2) the abscess is larger than 4 cm, or (3) the abscess increases in size while the patient is on medical therapy.

Percutaneous CT-guided catheter drainage has less morbidity and mortality than surgical resection does, and in most cases clinical and radiologic improvement occurs rapidly after catheter drainage. Although the mean time to abscess resolution is 10 to 15 days, marked improvement of sepsis (fever, leukocytosis) usually occurs within 48 hours of drainage. Failure of percutaneous drainage can occur when the abscess (1) contains viscous, organized tissue, (2) is multiloculated, or (3) has a thick, non-collapsible wall. Potential complications of lung abscesses drainage with a percutaneous tube include bleeding, bronchopleural fistula, and empyema.

PLEURAL AND CHEST WALL ABNORMALITIES

Malignant Pleural Mesothelioma

Malignant pleural mesothelioma (MPM) is an uncommon tumor that arises from mesothelial cells of the

pleura and less commonly of the pericardium or peritoneum. In the United States, it is estimated that there will be 2500 to 3000 cases per year, predominantly in older men, and the majority are associated with prior asbestos exposure.^{62,63}

Imaging is important not only in the diagnosis of MPM, but also in staging and monitoring of response to therapy.^{64,65} In an attempt to identify patients who are potentially resectable, the current staging for MPM emphasizes criteria used to determine local tumor extension and regional lymph nodes status in a traditional tumor node metastasis (TNM) system. The TNM staging system effectively distinguishes the T and N categories, but there are areas for potential revision. In this regard, by multivariable analyses, significant differences in overall survival were seen for: T4 versus T3 and T3 versus T2 but not T2 versus T1; N0 versus N1 and N2 but not N1 versus N2; stages III and IV versus I but not II versus I.⁶⁶⁻⁶⁸ Treatment options depend on the stage at presentation, with surgical resection sometimes performed in limited disease. Although the role of surgery (extrapleural pneumonectomy, extended pleurectomy/decortication) remains controversial, the presence of advanced locoregional primary tumor (T4), N2-3 disease (mediastinal, internal mammary, and supraclavicular lymph nodes), or M1 disease precludes resection.

MRI has historically been considered superior to CT in the staging of MPM. However, in a study comparing the accuracy of MRI and nonspiral CT in evaluation of MPM,⁶⁹ MRI and CT were found to have nearly equivalent diagnostic accuracies (50% to 65%) in overall staging. The only significant differences were in two categories: invasion of the diaphragm (CT accuracy, 55%; MRI accuracy, 82%; $P = 0.01$) and invasion of endothoracic fascia or a single chest wall focus (CT accuracy, 46%; MRI accuracy, 69%; $P = 0.05$). PET-CT is being used to evaluate patients with MPM (Fig. 2-13). PET-CT has improved the accuracy of tumor staging, and a sensitivity of 67% has been reported for T4 disease.⁷⁰ The sensitivity of PET-CT for detecting nodal metastatic disease is poor (i.e., 11% for PET alone and 38% for integrated PET-CT).^{70,71} PET-CT imaging is useful in detecting distant metastatic disease and has been reported to detect extrathoracic metastases that were not detected by clinical and morphologic imaging in 24% of patients with MPM.⁷⁰⁻⁷²

Pleural Collections

Fluid collections in the pleural space are caused by a variety of diseases, including infection, trauma, inflammation, and neoplasm. Although some patients can be managed conservatively, interventional procedures such as pleural fluid aspiration, with or without placement of a drainage catheter, or pleural biopsies are frequently performed for either diagnostic or therapeutic purposes. The type of intervention depends on a spectrum of clinical and imaging features, including symptoms, extent of disease, and etiology of the pleural abnormality. Imaging studies, most frequently with CT, can delineate the extent and complexity of the pleural collection.

FIGURE 2-13 ■ Malignant pleural mesothelioma. **A**, Posteroanterior chest radiograph shows moderate right pleural effusion and lobularity of the pleura. **B**, Axial fused positron emission tomography-computed tomography shows increased [¹⁸F] fluorodeoxyglucose uptake in pleural masses and focal uptake in subcarinal node (*asterisk*). Biopsy of subcarinal node revealed metastatic pleural mesothelioma, precluding extrapleural pneumonectomy.

Chest Wall Disease

Abnormalities of the chest wall are unusual and are most commonly the result of soft tissue tumors, metastatic disease, infections, iatrogenic causes, trauma, and congenital lesions. The choice of imaging modality for this spectrum of diseases often depends on the suspected etiology, but CT is usually the initial study for evaluation. Although CT can provide the requisite diagnostic information and has superb multiplanar capabilities for surgical planning, MRI is typically also performed; its superior soft tissue contrast resolution can be useful in accurately

FIGURE 2-14 ■ A 60-year-old man with newly diagnosed chondrosarcoma of the first rib presented with right shoulder pain. **A**, Contrast-enhanced axial chest computed tomography shows a large mass (M) arising from the right first rib. Note that the density of the mass is similar to that of muscle, as compared with the right pectoralis major muscle (P). The brachial plexus cannot be visualized. **B**, T2-weighted sagittal magnetic resonance imaging distinguishes the intensity of the mass (M) from that of surrounding soft tissues and muscles. This enables direct visualization of the right subclavian artery (black arrow) and brachial plexus (two black dots abutting tip of white arrow), which are surrounded by the tumor.

delineating the extent of involvement of the chest wall (Fig. 2-14).

POSTOPERATIVE IMAGING

Early awareness of surgical complications is important, as timely management is associated with a decrease in mortality. Chest radiographs commonly demonstrate abnormalities in patients after cardiothoracic procedures. An increase in heart size can be caused by perioperative

myocardial infarction or hypervolemia, although most frequently it is the result of fluid in the pericardial sac or mediastinal fat. In some cases, the mediastinal contours appear normal on chest radiographs even though a significant amount of bleeding has occurred. In other cases, the normal mediastinum may appear enlarged because of magnification effects on the supine, expiratory radiograph. CT can be used to evaluate mediastinal widening and air collections in patients after sternotomy, and it can be useful in suggesting the diagnosis of mediastinitis.⁷³

Pulmonary Embolism

Clinical signs and symptoms of pulmonary embolism (PE) are neither sensitive nor specific, because patients can have chest pain, shortness of breath, or oxygen desaturation. Initial imaging with chest radiographs is useful to search for other causes that can clinically mimic PE, such as pleural effusions, pneumothorax, pneumonia, or congestive heart failure. The chest radiographic findings in patients with PE are nonspecific and include consolidation, atelectasis, pleural effusion, peripheral wedge-shaped opacities, enlargement of a pulmonary artery, and focal oligemia. However, 80% of patients with PE have a normal chest radiograph.⁷⁴

If a diagnosis of PE is suggested, and the chest radiograph does not suggest a reasonable alternative diagnosis, other imaging modalities can be used for further evaluation. Multidetector CT angiography (CTA) is the method of choice for imaging the pulmonary vasculature when PE is suspected. In the Prospective Investigation of Pulmonary Embolism Diagnosis II (PIOPED II) study, pulmonary CTA had a sensitivity of 83% and specificity of 96% for the diagnosis of PE.⁷⁵ Additional advantages of using multidetector CTA to diagnose PE include the detection of alternative abnormalities that explain the patient's clinical presentation, the ability to quantify the obstruction to the pulmonary arterial bed,⁷⁶⁻⁷⁹ and the ability to predict 30-day mortality after acute pulmonary embolism by assessing cardiac strain as seen by an increase in right-left ventricular diameter ratios (Fig. 2-15).⁸⁰⁻⁸³ Pulmonary CTA is commonly acquired with low-pitch helical modes and without use of ECG synchronization (standard pulmonary CTA). More recently, a high-pitch helical CT technique with prospective ECG triggering has been reported to facilitate high-quality imaging with a decrease in radiation dose compared with standard CTA.⁸⁴

Evaluation of PE can also be performed with other imaging modalities such as conventional angiography, MRI, or ventilation-perfusion (V/Q) scans. Currently, because of the high sensitivity and specificity of CTA in detecting PE, as well as the ability to suggest alternative diagnoses, these modalities are infrequently used in the evaluation of patients with suspected PE. V/Q scans still have a role in the evaluation of PE disease in patients who are allergic to iodinated contrast agents or who have impaired renal function. In patients with a normal chest radiograph and a normal V/Q scan, there is a very low probability of pulmonary embolus, and no further evaluation for PE is required. Patients with a high pretest

FIGURE 2-15 ■ Pulmonary embolism and right ventricular strain. Contrast-enhanced axial multidetector computed tomography shows multiple filling defects in the segmental pulmonary arteries of the lower lobes (arrows). Note dilation of the right ventricle (RV) and right atrium (RA). The right ventricle is larger than the left ventricle (LV), and there is straightening of the interventricular septum. These findings are consistent with right heart strain.

probability of PE and a high-probability scan are likely to have pulmonary embolism, and treatment is often initiated. Single positron emission computed tomography (SPECT) V/Q can be used to improve the diagnosis of PE compared with planar V/Q. A prospective study reported a sensitivity of 100% and a specificity of 87% for SPECT V/Q, whereas planar V/Q scintigraphy had a sensitivity of 64% and a specificity of 72%.⁸⁵ Although magnetic resonance angiography (MRA) has been reported to have a similar negative predictive value compared with CTA-PE when used for the primary diagnosis of pulmonary embolism in symptomatic patients,⁸⁶ MRA has two main limitations that restrict acceptance as a second-line diagnostic test for PE diagnosis in patients with a contraindication to CTA: the limited sensitivity in detecting segmental and smaller emboli and the large proportion of technically inadequate studies.^{87,88} In this regard, 25% of the studies in the PIOPE III study evaluating contrast-enhanced MRA for PE diagnosis were technically inadequate for interpretation and sensitivity was 78%.⁸⁹ A further limitation of MRI is that the study can be technically challenging to perform, especially in the acute setting, in the postoperative patient, or in the patient in the intensive care unit. In addition, the use of MRI contrast agents is contraindicated in patients with impaired renal function, because of an association between gadolinium-based contrast agents and the development of nephrogenic systemic fibrosis.^{90,91} However, a recent study reported that whereas contrast-enhanced angiographic MRI sequences showed the highest sensitivity (82.9% to 89.7%) and specificity (98.5% to 100%), unenhanced angiographic sequences, although less sensitive overall (68.7% to 76.4%), were sensitive for the detection of proximal PE (92.7% to 100%) and showed high specificity (96.1% to 99.1%).⁹²

SUMMARY

Imaging plays an important role in the diagnosis and follow-up of patients with pulmonary diseases. Recent advances in imaging technologies have revolutionized evaluation of thoracic disease, with improvements in patient management. Careful selection of the appropriate imaging studies improves diagnostic accuracy, limits the number of tests performed, and decreases unnecessary surgery. It is anticipated that further improvement of existing modalities and continued development of novel imaging technologies will improve diagnostic imaging strategies and patient outcomes in the future.

PREOPERATIVE EVALUATION OF PATIENTS UNDERGOING THORACIC SURGERY

John J. Reilly, Jr.

CHAPTER OUTLINE	
PHYSIOLOGIC EFFECTS OF THORACIC SURGERY	IMAGING STUDIES
PATIENT POPULATION UNDERGOING THORACIC SURGERY	PULMONARY FUNCTION TESTING
COMMON COMPLICATIONS AFTER THORACIC SURGERY	PREDICTION OF POSTOPERATIVE LUNG FUNCTION
EFFECT OF SURGICAL APPROACH ON PERIOPERATIVE COMPLICATIONS	CARDIAC ASSESSMENT OF PATIENTS UNDER CONSIDERATION FOR THORACIC SURGICAL PROCEDURES
GOALS OF THE PREOPERATIVE EVALUATION	ASSESSMENT OF FUNCTIONAL CAPACITY
HISTORY AND PHYSICAL EXAMINATION	Arterial Blood Gas Measurements
History	Pulmonary Hemodynamics
Physical Examination	Age
Laboratory Studies	EVALUATION AND RISK STRATIFICATION

The decision to proceed with any surgical procedure involves a careful consideration of the anticipated benefits of surgery and an assessment of the risks associated with the surgical procedure. An important component of estimating the benefit of surgery is knowledge of the natural history of the condition in question in the absence of surgery.

A popular, and inaccurate, conception of preoperative evaluation is that the evaluating physician “clears” the patient for surgery. Implicit in this terminology is the assumption that a cleared patient has a low risk for perioperative morbidity. As will be discussed in this chapter, it is more accurate to view the role of preoperative evaluation as meeting two goals: defining the morbidity and risks of surgery, both short and long term, and identifying specific factors or conditions in patients that can be addressed to modify the patient’s risk of morbidity. The formulation of an approach to accomplish these goals requires knowledge of the effects of thoracic surgery on patients.

PHYSIOLOGIC EFFECTS OF THORACIC SURGERY

Surgical procedures and the anesthesia administered to allow such procedures have significant effects on

respiratory physiology that contribute to the development of postoperative pulmonary complications. Given that the incidence of pulmonary complications is directly related to the proximity of the planned procedure to the diaphragm, patients undergoing pulmonary, esophageal, or other thoracic surgical procedures fall into the category of patients at high risk for postoperative respiratory complication.¹

The intraoperative use of inhaled volatile agents can affect gas exchange by altering diaphragmatic and chest wall function. These changes occur without corresponding alterations in blood flow, which creates low ventilation-perfusion areas, resulting in widening of the alveolar-arterial oxygen gradient.

In the postoperative period, a variety of factors contribute to the development of complications; these include an alteration in breathing pattern to one of rapid shallow breaths with the absence of periodic deep breaths (sighs) and abnormal diaphragmatic function. These complications result both from pain and from diaphragmatic dysfunction resulting from splanchnic efferent neural impulses arising from the manipulation of abdominal contents. This has the effect of reducing the functional residual capacity (FRC)—the resting volume of the respiratory system. The FRC declines by an average of 35% after thoracotomy and lung resection and by

approximately 30% after upper abdominal operations.²⁻⁴ If the FRC declines sufficiently to approach closing volume, the volume at which small airway closure begins to occur, patients develop atelectasis and are predisposed to infectious complications. Closing volume is elevated in patients with underlying lung disease.

The alterations in lung volumes that occur result in a reduction in both the inspiratory capacity (the maximal inhalation volume attained starting from a given lung volume) and the expiratory reserve volume (the maximal exhalation volume from a given lung volume), contribute to a decline in the effectiveness of cough, and result in increased difficulty in clearing of pulmonary secretions.

PATIENT POPULATION UNDERGOING THORACIC SURGERY

Many patients undergoing a noncardiac thoracic surgical procedure do so because of known or suspected lung or esophageal cancer. These diseases share the common risk factor of a significant and prolonged exposure to cigarette smoking. The combination of age and prolonged cigarette smoking results in a patient population with a significant incidence of comorbid factors in addition to the primary diagnosis. Several reports use the Charlson Comorbidity Index as an indicator of comorbid conditions and predictor of postoperative complications. This index generates a score based on the presence of comorbid conditions; it has been demonstrated to stratify risk of postoperative complications in thoracic surgery patients.^{5,6}

In one study, the mean age of patients undergoing esophagectomy was 58.1 years; 45% of patients were older than 60 years.⁷ In another Japanese study, the median age was 62.3 years; 88% were male.⁸ In a study comparing transhiatal esophagectomy with transthoracic esophagectomy, the mean ages of the patients were 69 years and 64 years, with patients up to the age of 79 years being included in the study.⁹ In a review, 28% to 32% of patients undergoing esophagectomy in the United States were older than 75 years, and 40% had a Charlson score above 3.¹⁰

Similarly, patients with lung cancer tend to be older and have comorbid conditions. In a series of 344 patients, 36% were older than 70 years and 95% had a significant smoking history.¹¹ A review of Medicare patients undergoing thoracic surgery in the United States showed that of patients undergoing lobectomy, 32% to 35% were older than 75 years (44% women), and 32% had a Charlson score greater than 3.¹⁰ In the same series, 21% to 26% of patients undergoing pneumonectomy were older than 75 years (28% women), and 56% had a Charlson score above 3.

A significant source of comorbidity in the population of patients with lung cancer is chronic obstructive pulmonary disease (COPD). The diagnosis of COPD is an independent risk factor, controlling for cigarette smoke exposure, for the development of lung cancer.

Thus, the patient population presenting for major thoracic surgical procedures tends to be older, has a high incidence of comorbid conditions, and contains a

disproportionate number of patients with obstructive lung disease. The combination of these factors, plus the magnitude of the surgical procedures, presents a challenge to the clinicians evaluating such patients. The potential for perioperative morbidity and mortality is substantial, but at the same time, the lack of effective alternative therapy for the patient's malignant disease means that the consequence of not being a surgical candidate is almost certain mortality. This quandary has led Gass and Olsen¹² to ask: What is an acceptable surgical mortality in a disease with 100% mortality?

COMMON COMPLICATIONS AFTER THORACIC SURGERY

These are discussed in more detail elsewhere in this book (see [Chapter 4](#)). In general, the most frequent complications after major thoracic procedures fall into the categories of respiratory and cardiovascular. Although the exact frequency varies by series, pneumonia, atelectasis, arrhythmias (particularly atrial fibrillation), and congestive heart failure are the most common. Myocardial infarction, prolonged air leak, empyema, and bronchopleural fistula also occur at a significant frequency.^{11,13,14} It follows, therefore, that particular attention to pulmonary and cardiac reserve and risk factors should be a major component of the preoperative evaluation.

EFFECT OF SURGICAL APPROACH ON PERIOPERATIVE COMPLICATIONS

Two developments in thoracic surgical practice have had particular impact on the assessment of marginal candidates for thoracic surgical procedures. The first is the rise in the prevalence of "minimally invasive" approaches, including video-assisted thoracoscopic approaches, for both pulmonary parenchymal resections and esophageal surgery. The reported data suggest a lower rate of pulmonary complications after the use of thoracoscopic resection as compared with conventional thoracotomy, likely because of reduction in pain and improved chest wall mechanics.¹⁵ The second is the reemergence of lung volume reduction surgery and the recognition that a subset of patients with COPD have nonhomogeneous distribution of emphysema with an upper-lobe predominance, which is also the most common site of non-small-cell lung cancer, and that upper lobe resection in such individuals produces less deleterious impact on measured pulmonary function and in some instances can result in improvement in measured lung function after resection.¹⁶

GOALS OF THE PREOPERATIVE EVALUATION

The clinicians evaluating a patient for a major thoracic surgical procedure have several goals for the evaluation process. The most obvious of these goals is to provide all parties with an assessment of the risks, both short and

long term, of morbidity and mortality from the procedure in a given patient and simultaneously to identify factors that can be addressed to reduce the possibility of adverse events. Less obvious is that the comprehensive evaluation of a patient as part of the preoperative assessment allows the identification of risk factors and health issues independent of the planned surgery and facilitates the institution of interventions indicated regardless of plans for surgery.

HISTORY AND PHYSICAL EXAMINATION

Although the field of thoracic surgery has been dramatically altered by the development of new technologies in both imaging and therapeutics, the history and physical examination remain the most important components of the preoperative evaluation. There is no substitute for a careful history and examination by an experienced clinician.

History

Box 3-1 highlights the important components of the patient's history. Whereas many of the elements of the history are self-explanatory, several benefit from further exposition. A critical component of the preoperative evaluation is the assessment of a patient's functional status. Functional status is an important component of the decision algorithm for both the pulmonary and cardiac elements of the preoperative evaluation. A variety of approaches have been taken to determine functional capacity. These include questionnaires; tests of locomotion, such as the 6-minute walk or stair climbing; and cardiopulmonary exercise testing (discussed later). One convenient approach to use is the Duke Activity Status Index (DASI; [Table 3-1](#)), a questionnaire that can be administered during an interview or be self-administered.¹⁷

There is a rough correlation between the score on the DASI, which ranges from 0 to 58.2, and maximal oxygen uptake. In addition, the answers to this questionnaire can be used to estimate the functional capacity of the patient in metabolic equivalents (METs), a common frame of reference used in structuring the approach to

preoperative cardiac evaluation (discussed later). Four METs is the energy expenditure required to climb a flight of stairs, to walk up a hill or briskly on level ground, or to run a short distance (items 3 to 5 on the DASI); 1 to 4 METs are required to perform self-care, to ambulate on level ground within a residence, and to perform light housework (items 1, 2, 3, and 6 on the DASI). More than 10 METs are required to participate in strenuous sports such as singles tennis, bicycling, or basketball (item 12 on the DASI).

In addition to these considerations, patients should be asked about signs or symptoms suggesting the presence of metastatic disease, such as new headaches, focal neurologic signs or symptoms, new-onset seizure disorder, bone pain, and recent fractures. Patients should also be questioned about symptoms related to paraneoplastic syndromes. These can range from the relatively subtle symptoms of hypercalcemia to more dramatic neurologic symptoms.

Physical Examination

The examination of the patient includes an assessment of general overall appearance, including signs of wasting. Respiratory rate and the use of accessory muscles of

BOX 3-1 Important Components of History in Preoperative Evaluation

- Presenting symptoms and circumstances of diagnosis
- Prior diagnosis of pulmonary or cardiac disease
- Comorbid conditions: diabetes mellitus, liver disease, renal disease
- Prior experiences with general anesthesia and surgery
- Cigarette smoking: never, current, ex-smoker (if ex-smoker, when did patient stop?)
- Inventory of functional capacity of patient (e.g., Duke Activity Status Index)
- Medications and allergies
- Alcohol use, including prior history of withdrawal syndromes

TABLE 3-1 Duke Activity Status Index

Question	Activity: Can You	Yes	No
1	Take care of yourself, that is, eating, dressing, bathing, or using the toilet?	2.75	0
2	Walk indoors, such as around your house?	1.75	0
3	Walk a block or two on level ground?	2.75	0
4	Climb a flight of stairs or walk up a hill?	5.50	0
5	Run a short distance?	8.00	0
6	Do light work around the house like dusting or washing dishes?	2.70	0
7	Do moderate work around the house like vacuuming, sweeping floors, or carrying in groceries?	3.50	0
8	Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture?	8.00	0
9	Do yard work like raking leaves, weeding, or pushing a power mower?	4.50	0
10	Have sexual relations?	5.25	0
11	Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football?	6.00	0
12	Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?	7.50	0

From Hlatky MA, Boineau RE, Higginbotham MB, et al: A brief self-administered questionnaire to determine functional capacity (the Duke Activity Status Index). *Am J Cardiol* 64:651–654, 1989.

respiration are noted. Examination of the head and neck includes assessment of adenopathy and focal neurologic deficits or signs, particularly Horner syndrome in patients with a lung mass. The pulmonary examination includes an assessment of diaphragmatic motion (by percussion) and notes any paradoxical respiratory pattern in the recumbent position. The relative duration of exhalation and the presence or absence of wheezing should be noted. The presence of rales should raise the possibility of pneumonia, heart failure, or pulmonary fibrosis. The cardiac examination includes assessment of a third heart sound to suggest left ventricular failure, murmurs to suggest valvular lesions, and an accentuated pulmonic component of the second heart sound suggestive of pulmonary hypertension. The heart rhythm and the absence or presence of any irregular heart beats are noted. The abdominal examination notes liver size, presence or absence of palpable masses or adenopathy, and any tenderness. The examination of extremities notes any edema, cyanosis, or clubbing. Clubbing should not be attributed to COPD and raises the possibilities of intrathoracic malignant disease or congenital heart disease. The patient's gait should be observed, both as an assessment of neurologic function and to confirm the patient's ability to participate in postoperative mobilization.

Laboratory Studies

It is reasonable practice to check electrolyte values, renal function, and clotting parameters and to obtain a complete blood count as part of the preoperative assessment. In patients with known or suspected malignant disease, liver function and serum calcium concentration should also be checked.

IMAGING STUDIES

This issue is covered in detail elsewhere in this text. For patients undergoing pulmonary parenchymal resection, a review of images is essential to estimate the amount of lung that will be removed in surgery. In this setting, patients usually have a computed tomographic (CT) scan of the chest. In addition to the pathologic process for which the patient has been referred, the scan should be reviewed for signs of emphysema or pulmonary fibrosis. As noted earlier, the distribution of emphysema (if present) may significantly affect postoperative lung function. In general, review of images is an important component of surgical planning and determination of the extent of resection, which in turn influences the process of evaluation of the patient.

PULMONARY FUNCTION TESTING

The utility of preoperative pulmonary function testing in part depends on the type of operative procedure being planned. For patients undergoing mediastinoscopy, drainage of pleural effusions, or pleural biopsy or esophageal surgery and who have no prior history of lung disease or unexplained dyspnea, preoperative pulmonary

function testing is unlikely to contribute to the preoperative evaluation.

For patients being considered for pulmonary parenchymal resection, preoperative pulmonary function testing should be performed. Although a variety of pulmonary function tests have been examined in this setting, the two that have emerged as being predictive of postoperative complications are the *forced expiratory volume in 1 second* (FEV₁) measured during spirometry and the *diffusing capacity for carbon monoxide* (DL_{CO}). The diffusing capacity is also referred to as the *transfer factor*. Both of these values can be used to provide a rough estimate of the risk of operative morbidity and mortality. In addition, they are used to calculate the *predicted postoperative* values for FEV₁ and DL_{CO} (ppo-FEV₁ and ppo-DL_{CO}, respectively).

PREDICTION OF POSTOPERATIVE LUNG FUNCTION

Predicted postoperative lung function has been demonstrated to be an important predictor of operative risk. In general, the available methods for calculation of postoperative lung function result in an underestimate of actual measured lung function once the patient has recovered from surgery. Two approaches are commonly used for calculation of postoperative lung function: simple calculation and the regional assessment of lung function.

Simple calculation is based on the assumption of homogeneously distributed lung function, and it requires knowledge of the number of segments to be resected and the preoperative value. For FEV₁, the formula is $\text{ppo-FEV}_1 = \text{FEV}_1 [1 - (\text{Number of segments resected} \times 0.0526)]$. A similar calculation is done for DL_{CO}. For the majority of patients, this approach to calculation is sufficient and, as mentioned before, it results in a postoperative predicted value that is somewhat less than what is measured after recovery.

In certain situations, simple calculation is inaccurate in predicting postoperative lung function. The clinical situations in which regional assessment of lung function is indicated are summarized in [Box 3-2](#). A variety of approaches have been used to attempt to assess the regional distribution of lung function, including lateral position testing, bronchosprometry, quantitative radionuclide ventilation-perfusion scanning, and quantitative

BOX 3-2

Indications for Preoperative Assessment of the Regional Distribution of Lung Function

- Significant air flow obstruction on spirometry (FEV₁ < 80% predicted and FEV₁/FVC < 0.70)
- Significant pleural disease
- Known or suspected endobronchial obstruction
- Central lung mass
- History of prior lung resection

FEV₁, Forced expiratory volume in 1 second; FVC, forced vital capacity.

CT scanning. The test that is used most frequently is radionuclide scanning. Typically, the data from quantitative radionuclide ventilation-perfusion scans are reported as the percentage of function contributed by six lung regions: upper third, middle third, and lower third of each hemithorax. These data, combined with the knowledge of the preoperative lung function value and the location and planned extent of resection, allow the calculation of a predicted postoperative value. An alternative approach is the use of quantitative CT scanning, which categorizes lung tissue with an attenuation between -910 and -500 Hounsfield units as “functional lung tissue,” and in a manner analogous to that used for radionuclide scanning, an estimate of remaining functional lung tissue can be made on the basis of knowledge of the extent of planned resection.¹⁸ Comparison with radionuclide scanning suggests that quantitative CT scanning correlates with measured postoperative function as well as or better than radionuclide scanning does.¹⁹ This approach also allows prediction of postoperative oxygen saturation, which in turn has a correlation with postoperative complications and recovery time.²⁰ Similar to other methods of predicting postoperative lung function, it may underestimate residual function in patients with COPD.²¹ Despite these data and the potential advantages of using the CT scan for both anatomic definition and functional calculations, eliminating the need for the additional time and expense of a radionuclide perfusion scan, it has not been widely adopted (see [Box 3-2](#)).

CARDIAC ASSESSMENT OF PATIENTS UNDER CONSIDERATION FOR THORACIC SURGICAL PROCEDURES

The basic philosophy of cardiac assessment for surgical procedures has changed in recent years, as reflected in the recently released Clinical Practice Guideline: 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery.²² The preoperative evaluation is now viewed as an opportunity to perform a general cardiac assessment and to initiate risk factor modification or management rather than a specific intervention centered on surgery. The practice is to institute medical management as indicated by the patient's condition, rather than specific preoperative recommendations. In keeping with this approach, current concepts are that coronary revascularization, by either catheter approach or bypass grafting, is rarely indicated solely to reduce operative risk in a particular patient.

The preoperative cardiac evaluation incorporates both the cardiac risks associated with the operation under consideration and the specific risk factors of the particular patient under consideration. In general, thoracic surgical procedures fall into the risk categories of high (cardiac risk $> 5\%$, operations with an anticipated long procedure time, major fluid shifts, or blood loss) and intermediate (cardiac risk $1\%-5\%$, intrathoracic surgery). Given this and the above-referenced demographic and risk factors of the population of patients undergoing thoracic

surgery, a 12-lead ECG should be a routine part of the preoperative evaluation.

As with the evaluation in general, the cornerstone of preoperative cardiac evaluation is a careful history and physical examination. In addition to inquiries directed at cardiac risk factors such as family history, smoking history, history of hypercholesterolemia, history of diabetes mellitus or hypertension, and history of prior cardiac disease, special attention is directed to questions to assess the patient's functional capacity, as discussed previously. The combination of the classification of clinical predictors, the patient's functional capacity, and the risk of surgery then determines the approach to preoperative evaluation. Since the prior edition of this text, several instruments to predict the risk of perioperative major adverse cardiac events have been developed and are widely available. Two of the more commonly used instruments have been developed by the American College of Surgeons: <http://www.surgicalriskcalculator.com/miocardiacarrest> and <http://www.riskcalculator.facs.org>.^{23,24} The latter also provides risk estimates for noncardiac complications and outcomes, but requires more data for its calculations.

Current guidelines recommend a stepwise approach to the evaluation after a comprehensive history, physical examination, and review of the electrocardiogram. If a patient has had coronary revascularization within the past 5 years and has not had a clinical change since then, or if the patient has had a cardiac evaluation within the past 2 years that did not demonstrate the patient to be at high risk, further testing is usually not indicated. If neither of these considerations applies, the next step is to classify patients according to their clinical predictors.

For patients with a history of myocardial infarction within 30 days, unstable coronary syndromes, decompensated congestive heart failure, significant arrhythmias, or severe valvular disease, delay of the procedure should be considered for all but emergency procedures. Such patients should have medical risk factor management and modification initiated, and consideration should be given to performing coronary angiography.

Patients with good functional capacity (defined as ≥ 4 METs) and no cardiac symptoms should proceed with the planned surgery. Patients with unknown functional status or other medical conditions, such as orthopedic or neurologic issues that affect functional status, should be considered for pharmacologic stress testing. In individuals with unexplained dyspnea or with a history of congestive heart failure and a recent increase in dyspnea or reduction in exercise capacity, evaluation of left ventricular function with echocardiography should be considered.²² Although recent data suggest that beta blockers can be used safely in acutely ill patients with COPD, the role of beta blockers in perioperative management is unclear.²⁵ Current recommendations are that individuals using beta blockers long term have these agents continued during the perioperative period. The data supporting the initiation of beta blockers for reducing perioperative complications is more complicated and do not clearly establish the benefit of a policy of prescribing them routinely.²² The approach to preoperative cardiac evaluation is summarized in [Figure 3-1](#).

FIGURE 3-1 ■ Cardiac evaluation algorithm. ACC, American College of Cardiology; AHA, American Heart Association; CHF, chronic heart failure; HR, heart rate; METs, metabolic equivalents; MI, myocardial infarction. (Modified from Fleisher LA, Fleischmann KE, Auerbach AD, et al: 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery. *J Am Coll Cardiol* 64[22]:e77–e137, 2014.)

For all patients, any long-term issues meriting consideration of risk factor modification or therapy should be addressed in the postoperative period. Appropriate therapy is instituted when the patient is stable enough to tolerate it.

ASSESSMENT OF FUNCTIONAL CAPACITY

For patients undergoing pulmonary resection, functional capacity is an important predictor of postoperative morbidity and mortality. In addition to the role of functional capacity in determining the appropriate cardiac evaluation before surgery (see Fig. 3-1), functional capacity has predictive value for postoperative complications independent of that derived from pulmonary function testing.

In clinical practice, in addition to patient-reported functional status (described previously), there are two common approaches to objective assessment of functional capacity: (1) symptom-limited maximal cardiopulmonary exercise testing with expired gas analysis, and (2) threshold testing, which requires patients to attain a certain functional goal. Among the latter, the most commonly used test is stair climbing. Published data on stair climb testing suggest that patients who can climb more than three flights (54 steps) are at acceptable risk for lobectomy and that patients who can climb more than 4.6 to 5 flights are at acceptable risk for pneumonectomy. Conversely, patients unable to climb more than 12 m on

a symptom-limited stair-climbing test are at high risk for perioperative morbidity and mortality.^{11,26-33} An alternative to stair climbing is the shuttle walk, in which subjects walk back and forth (“shuttle”) on a 10-m course at a pace cued by an audio signal, increasing in speed every minute until the subject is too breathless to maintain the target pace. A result of less than 25 shuttles has been reported to correlate with maximal oxygen uptake (see later) of less than 10 mL/kg/min and, by inference, with prohibitive operative risk.³⁴

Maximal symptom-limited cardiopulmonary testing has been studied as a mode of assessment of functional capacity. The most commonly reported result of such testing is the maximal oxygen uptake ($\dot{V}O_2$) normalized for body mass, expressed as milliliters per kilogram per minute. Alternatively, the data are reported as a percentage of predicted value. There is good agreement that patients with an $\dot{V}O_2$ of more than 15 to 20 mL/kg/min are at low or “acceptable” risk for perioperative complications and mortality.³⁵⁻³⁷ Conversely, patients with an $\dot{V}O_2$ of less than 10 to 12 mL/kg/min are at high risk for thoracic surgery.^{33,38-40} In addition to these applications, the preoperative $\dot{V}O_2$ can also be used in concert with a regional assessment of lung function to calculate a predicted postoperative $\dot{V}O_2$ (ppo- $\dot{V}O_2$), in a manner analogous to that described for lung function parameters.³⁹ The ppo- $\dot{V}O_2$ can then be used to stratify perioperative risk.

Currently available data suggest that patients with a predicted postoperative FEV₁ or DL_{CO} of less than 40% should have additional risk stratification with a test of functional capacity. An alternative sequence of evaluation has been assessed by Bolliger and Perruchoud,⁴¹ who advocate functional assessment in all patients with an FEV₁ or DL_{CO} less than 80% predicted and reserve regional assessment of lung function for patients with a maximal oxygen uptake of 10 to 20 mL/kg/min or 40% to 75% of predicted. A synthesis of current recommendations for preoperative evaluation for pulmonary resection is presented in Figure 3-2.⁴²

Arterial Blood Gas Measurements

Commonly measured preoperatively, arterial blood gases have been used to attempt to stratify the risk of perioperative complications. Reports on the utility of arterial oxygen saturation in preoperative evaluation are contradictory; some suggest that resting hypoxemia or exertional desaturation identifies patients at higher risk, but others fail to confirm this association.^{43,44} This has led to the recommendation that patients with resting SaO₂ less than 90% undergo further physiologic evaluation.⁴² Patients with a resting PCO₂ greater than 45 mm Hg are at increased risk.^{35,45} Several studies, however, have demonstrated that resection can be undertaken safely in patients with resting hypercarbia in the absence of other contraindications to surgery.^{14,35,46}

Pulmonary Hemodynamics

Measurements of resting pulmonary hemodynamics, pulmonary artery occlusion, or exercise hemodynamics have

FIGURE 3-2 ■ Preoperative evaluation algorithm. CPET, Cardiopulmonary exercise testing; CT, computed tomography; DL_{CO} , diffusing capacity for carbon monoxide; FEV_1 , forced expiratory volume in 1 second; $M\dot{V}O_2$, maximal oxygen uptake; ppo, predicted postoperative; SaO_2 , arterial oxygen saturation.

been studied as preoperative assessments. The data generated are contradictory and generally do not add substantially to information obtained from functional assessment and pulmonary function testing.³⁰

Age

Although age has been confirmed in many series as a risk factor for perioperative complications, much of the additional risk from age results from comorbid factors. When studies control for comorbidities, patients are at mildly (approximately twofold) increased risk because of age.⁴⁷ Current consensus is that age alone, particularly in the presence of a good functional capacity, is not a contraindication to surgery.^{32,42}

EVALUATION AND RISK STRATIFICATION

Table 3-2 presents parameters that identify patients at higher and lower risk for complications after pulmonary surgery. Building on these parameters, various authors have attempted to create a multifactor risk assessment tool that incorporates a variety of these parameters.⁴⁸ A recommended approach to the preoperative evaluation, based on recent published consensus guidelines, is presented in Figure 3-2.⁴² Patients who fall into the conventional category of high or prohibitive risk and who are candidates for lung volume reduction surgery by virtue of having severe air flow obstruction and upper lobe-predominant emphysema may be candidates for parenchymal resection if the lesion requiring resection falls within the tissue that would be resected as part of lung

TABLE 3-2 Risk Assessment for Pulmonary Surgery

Higher Risk	Lower Risk
Age > 70 years	FEV_1 : >2 L for pneumectomy; >1.5 L for lobectomy; >0.6 L for segmentectomy
Higher extent of resection (pneumectomy, lobectomy, wedge resection)	Predicted postoperative FEV_1 > 30%-40%
Poor exercise performance	Stair climbing: >5 flights for pneumectomy; 3 flights for lobectomy
Low predicted postoperative FEV_1	Cycle ergometry > 83 watts
Low predicted postoperative DL_{CO}	Predicted postoperative DL_{CO} > 40%
Prolonged operative time	Maximal oxygen uptake > 15-20 mL/kg/min

DL_{CO} , Diffusing capacity for carbon monoxide; FEV_1 , forced expiratory volume in 1 second.

volume reduction. In this case, the predicted postoperative FEV_1 would actually be higher than that measured preoperatively, and standard prediction algorithms would not apply (see Table 3-2 and Fig. 3-2).⁴⁹⁻⁵²

DISCHARGE PLANNING

Patients who are undergoing thoracic surgery require careful attention in the perioperative period. These patients are often older and have baseline abnormalities of lung function, decreased nutritional status, and other comorbid diseases. Postoperatively, factors that influence patient recovery include removal of all or a portion of a lung, the esophagus, or the chest wall, painful incisions, retention of secretions, change in the shape and mechanics of the thoracic cage, and reconfiguration of gastrointestinal continuity, which result in suboptimal pulmonary function, decreased appetite, decreased mobility and strength, and increased risk of aspiration.

Perioperative care of the thoracic surgical patient requires a team approach. The surgeon is uniquely qualified to be the captain of the team, because he or she is aware of the patient's functional status preoperatively,

the operative findings and events, and the postoperative anatomy that will dictate each patient's needs and restrictions. Members of the team include the surgeon, anesthesiologist, pain management specialist, nurse, respiratory therapist, physical therapist, pharmacist, occupational therapist, speech pathologist, dietician, and social worker.

By the year 2030, an estimated 70 million people will be older than 65 years. A Surveillance, Epidemiology, and End Results study of lung cancer in older patients found that 14% and 33% of lung cancer patients were older than 80 years and 70-79 years, respectively.¹ In addition to evaluating the medical benefit of thoracic surgical procedures in the elderly, the effects on baseline functioning, living situation, and quality of life need to be assessed. Multiple different assessment tools predict the risk of

mortality or morbidity for these patients. Although no tool is perfectly accurate or reliable, they can be helpful for deciding whether to perform surgery, the extent of surgery, surgical approach, and hospital discharge planning and disposition.²⁻⁴

For palliative procedures, a discussion of the patient's expected outcome from the operation—symptomatically, medically, and functionally—is prudent to ensure that the patient and family understand the benefit/risk balance of each procedure and want to move forward. Knowledge of advanced directives and Do Not Resuscitate or Do Not Intubate status before the operation is recommended.⁵

In recent years, there has been increased focus on patient safety, quality of patient care, and cost savings. As care becomes more specialized, duty hours are restricted, and more practitioners become involved in each patient's care, communication between team members and hand-offs will be critical for safe patient care. Clinical pathways, protocols for patient updates and practitioner shift changes, and checklists are tools that have been developed and implemented. Some protocols have been assessed, whereas others need further study to ensure that they address the need for cost-effective, high-quality, standardized, and error-free patient care.⁶⁻⁸

PREOPERATIVE PREPARATION

An in-depth review of preoperative assessment is covered in [Chapter 3](#). Medical optimization for thoracotomy or thoracoscopy patients includes adjustment of medications for chronic obstructive pulmonary disease, including administration of bronchodilators and steroids and treatment of acute bronchitis or pneumonia.⁹ Total resolution might not be possible if the pneumonia is caused by a postobstructive process secondary to lung mass or chronic aspiration from gastroesophageal reflux disease.

Patients with borderline pulmonary function can benefit from pulmonary rehabilitation that increases their exercise tolerance and respiratory muscular strength before the resection.¹⁰⁻¹³ Preoperative pulmonary rehabilitation should be a routine component for all patients undergoing lung volume reduction surgery.^{10,14,15} Smoking cessation not only affects overall health; it also decreases postoperative morbidity and mortality of thoracic surgery.¹⁶ Support groups, counseling, nicotine replacement therapy, and pharmacologic treatment are available and successful.¹⁷ If there is no smoking cessation program associated with the provider's hospital, programs can be located by calling the local American Lung Association. Timing of smoking cessation before the operation remains debatable. Because of the number of conflicting studies, space does not allow review of this issue. Our current recommendation is that all smokers requiring lung resection should be encouraged to quit smoking, and assisted to do so, at any time before surgery.¹⁸⁻²²

Additional comorbid diseases that need to be managed include coronary artery disease, diabetes mellitus, and myasthenia gravis. The American Heart Association and the American College of Cardiology classify thoracic surgical procedures as medium risk. When there is no

clinical history of risk factors for cardiac disease, no further workup is necessary if a preoperative 12-lead electrocardiogram (ECG) is normal.^{23,24} If a patient has risk factors for cardiac disease, further testing should be done to assess the presence and degree of disease. However, revascularization for significant coronary stenosis simply to decrease risk of perioperative ischemic event has not been proved beneficial to overall survival.²⁵ Medical optimization with therapy such as β -blocker, statin, and after-load reduction and continuance of aspirin given for coronary disease is recommended.²⁶

Diabetic patients should have their cardiac, renal/intravascular volume, and glucose status checked before elective surgery, although there is controversy regarding rapid adjustment of chronic hyperglycemia in patients with diabetes. Electrolytes should be checked preoperatively, and abnormalities should be treated. Baseline creatinine measurement is helpful. Acute elevation in creatinine needs to be investigated before elective thoracic surgery. Orthostatic vital signs should be also performed.^{27,28}

Diabetic patients optimally should have good glycemic control preoperatively. Some guidelines recommend checking HbA1c and adjusting medications for better glucose control before the operation if time permits in patients with diabetes. However, other studies have shown no improvement in outcome and some adverse reactions from rapid glucose control in the weeks to months preceding elective noncardiac surgery.²⁹ Long-acting sulfonylureas and thiazolidinediones should be discontinued 24 to 48 hours before elective surgery. Shorter-acting sulfonylureas, secretagogues such as metformin, or GLP-1 agonists can be stopped 12 hours before surgery. DPP-4 inhibitors can be continued preoperatively. Long-acting insulin can be continued until the day of surgery if control has been good. If there is glucose level fluctuation, long-acting insulin should be stopped 24 to 48 hours before surgery, and sliding-scale insulin should be used with frequent glucose checks.^{27,28}

Another challenge is the patient who is not aware that they have diabetes mellitus. Perioperative complications can be decreased, and long term well-being will be affected with discovery and treatment of undiagnosed diabetes. Therefore, we recommend that patients having thoracic surgery be evaluated for diabetes preoperatively if they are older than 45 years or are younger and overweight with 1 or more of the risk factors shown in [Box 4-1](#) by testing a fasting glucose level or HbA1c.^{23,29}

For patients with myasthenia gravis, the goal of preoperative preparation is to reduce the risk of myasthenic crisis, which is acute respiratory muscle malfunction leading to respiratory failure. Medication and treatment adjustments may be needed to maintain adequate function for daily living until the time of surgery. Doses of steroids and anticholinesterase medication should be tailored to the patient's symptoms. More aggressive and rapid therapies include infusion of intravenous immune globulin and plasmapheresis, and they have effects lasting weeks to months.³⁰ Plasmapheresis usually requires multiple exchanges, and it is recommended for patients with a vital capacity of less than 2.0 L.

BOX 4-1**Criteria Used to Screen for Diabetes Mellitus: ADA and USPSTF****AMERICAN DIABETES ASSOCIATION***

1. Testing should be considered in all adults who are overweight (BMI ≥ 25 kg/m²) and have additional risk factors:
 - Physical inactivity
 - First-degree relative with diabetes
 - Members of high-risk ethnic populations
 - Women who delivered a baby weighing greater than 9 pounds or were diagnosed with GDM
 - Hypertension
 - HDL cholesterol <35 mg/dl or triglycerides >250 mg/dl
 - Women with PCOS
 - IGT or IFG on prior testing
 - Other clinical conditions associated with insulin resistance
 - History of cardiovascular disease
2. In the absence of aforementioned criteria, testing for diabetes and prediabetes should begin at age 45 years.
3. If the results are normal, testing should be repeated at 3-year intervals, with consideration of more frequent testing depending on initial results and risk status.

U.S. PREVENTIVE SERVICES TASK FORCE

- Screen is recommended for asymptomatic adults with sustained blood pressure greater than 135/80 mm Hg.
- No recommendation for asymptomatic adults with blood pressure less than 135/80 mm Hg.

PROPHYLAXIS**Atrial Fibrillation**

The incidence of postoperative atrial fibrillation ranges between 3% and 30% in thoracic surgical patients. It increases the risk of stroke and prolongs postoperative length of stay, thus increasing hospital cost.³¹ Multiple risk factors are associated with development of atrial fibrillation after thoracic surgery including patient factors such as age, male sex, history of congestive heart failure, and previous history of atrial fibrillation. Procedural risk factors include length of procedure and dissection near the atria or pericardium.³² A retrospective review of more than 2900 patients revealed increased relative risks of atrial fibrillation of 3.89, 7.16, 8.91, and 2.95 for lobectomy, bi-lobectomy, pneumonectomy, and esophagectomy, respectively, compared with a single wedge resection.³¹ Numerous studies on the prevention and treatment of postoperative atrial fibrillation have been performed, but the majority were for cardiac surgical

patients. The Society of Thoracic Surgeons released guidelines regarding prophylaxis and treatment of atrial fibrillation in association with general thoracic surgery.³² Prophylaxis recommendations include resuming β -blockade if the patient was taking a β -blocker beforehand, or the use of diltiazem, amiodarone, or a β -blocker if the patient was not taking preoperative β -blockers for lobectomy patients. The use of amiodarone for prophylaxis is not recommended for patients undergoing pneumonectomy. Magnesium supplementation has been shown to be helpful for atrial fibrillation prophylaxis.

For atrial fibrillation with rapid ventricular response, rate control is the main priority. Conversion back to normal sinus rhythm is a secondary, but not an immediate goal unless there is hemodynamic instability.

Deep Venous Thrombosis

Postoperatively, a majority of thoracic surgery patients are slow to move because of pain, respiratory distress, and age. Venous thromboembolism (VTE) includes deep venous thrombosis and pulmonary embolism and causes an estimated 300,000 deaths annually in the United States. VTE prophylaxis could prevent 100,000 of these deaths.³³ The current recommendations for deep venous thrombosis prophylaxis from the American College of Chest Physicians vary depending on patient risk. A useful risk stratification model is the Caprini scoring system, which has been validated for general, vascular, urologic, and plastic and reconstructive surgery (Table 4-1).³⁴ The risk of VTE is even greater in patients undergoing treatment for cancer.^{33,35} VTE prophylaxis is not recommended for outpatients undergoing thoracic surgery (Box 4-2).³⁵

Stress Ulceration and Gastritis

Stress ulceration prophylaxis is recommended in critically ill patients with coagulopathy, expected mechanical ventilation for longer than 48 hours, on antiplatelet or anticoagulant medications, a history of gastrointestinal bleeding or gastric ulceration in the past year, and at least two of the following: sepsis, intensive care unit stay longer than 1 week, high-dose steroid administration, or occult bleeding lasting 6 or more days.³⁶ The incidence of clinically significant bleeding remains low with the use of pharmacologic agents for prophylaxis in these high-risk patients. The risk of gastritis and stress ulceration in patients without risk factors is low; therefore, routine prophylaxis is not recommended. Multiple studies have evaluated the use of proton pump inhibitors (PPIs) compared with histamine 2 receptor blockers (H₂ blockers) with respect to incidence of bleeding and incidence of nosocomial pneumonia. The data are not strong, and the use of either PPI or H₂ blockers for high-risk patients is recommended for the duration of their time in intensive care, but may not be necessary when patients are no longer critically ill or are discharged from the hospital. In addition, PPI may be associated with a higher rate of nosocomial pneumonia, whereas H₂ blockers can interfere with other medications metabolized by the P450 cytochrome pathway.^{36–39}

BOX 4-2 ASCO Guideline: Venous Thromboembolism Prophylaxis and Treatment in Patients with Cancer

INTERVENTIONS

- Pharmacologic anticoagulation

TARGET AUDIENCE

- Medical oncologists, surgical oncologists, hospitalists, oncology nurses

KEY RECOMMENDATIONS

- Most hospitalized patients with cancer require thromboprophylaxis throughout hospitalization.
- Thromboprophylaxis is not routinely recommended for ambulatory patients with cancer; it may be considered for select high-risk patients.
- Patients with multiple myeloma receiving antiangiogenesis agents with chemotherapy or dexamethasone should receive prophylaxis with either LMWH or low-dose aspirin to prevent VTE.
- Patients undergoing major cancer surgery should receive prophylaxis starting before surgery and continuing for at least 7 to 10 days.

- Extending postoperative prophylaxis up to 4 weeks should be considered in those with high-risk features.
- LMWH is recommended for the initial 5 to 10 days of treatment for patients with established deep vein thrombosis and pulmonary embolism, as well as for long-term (6 months) secondary prophylaxis.
- Use of novel oral anticoagulants is not currently recommended for patients with malignancy and VTE.
- Anticoagulation should not be used to extend survival in patients with cancer in the absence of other indications.
- Patients with cancer should be assessed periodically for VTE risk.
- Oncology professionals should provide patient education about the signs and symptoms of VTE.

METHODS

- An expert panel was convened to develop clinical practice guideline recommendations based on a review of evidence provided by a systematic review of the medical literature.

Infection

A properly timed dose of intravenous first-generation cephalosporin is efficacious in preventing wound infections from skin pathogens. For patients with β -lactam allergy, vancomycin or intravenous clindamycin are the substitutes of choice.⁴⁰ Vancomycin administration must be started early enough to ensure that the dose is completely infused before the first incision. There are

insufficient data to support the administration of more than one dose of prophylactic antibiotic for elective non-transplant thoracic surgical procedures. If the prophylactic antibiotic is continued beyond the preoperative dose, no data have supported the use of antibiotic beyond 24 hours for wound prophylaxis (Table 4-2).⁴⁰

Prophylaxis for pneumonia and empyema in patients undergoing lung resection or esophageal resection is an attractive concept, because these prophylaxes involve

TABLE 4-2 Perioperative Antimicrobial Recommendations for Thoracic Surgery

Procedure	Common Pathogens	Antibiotic Regimen
Pulmonary resections	<i>Staphylococcus aureus</i> Coagulase-negative staphylococci <i>Streptococcus pneumoniae</i>	Cefazolin 1 g IV preoperatively, with a total of 1-3 doses every 8 hours If penicillin allergic, vancomycin 1 g IV preoperatively, with a total of 1-3 doses every 12 hours
Esophageal surgeries	Gram-negative bacilli Enteric gram-negative bacilli Streptococci Oropharyngeal anaerobes	Cefazolin 1 g IV preoperatively, with a total of 1-3 doses every 8 hours If penicillin allergic, vancomycin 1 g IV preoperatively, with a total of 1-3 doses every 12 hours If high anaerobic burden likely, cefepime 1 g IV preoperatively, with a total of 1-3 doses every 12 hours
Lung transplantation	<i>Pseudomonas</i> spp. <i>Burkholderia cepacia</i> Gram-negative bacilli Methicillin-resistant <i>Staphylococcus aureus</i> Cytomegalovirus <i>Candida</i> spp. <i>Aspergillus</i> spp. <i>Pneumocystis carinii</i>	Cefepime 1 g IV preoperatively, with a 7-10 day course* For cystic fibrosis patients, sensitivities are sent and for multidrug-resistant <i>Pseudomonas</i> spp., inhaled colistin should be added perioperatively Vancomycin 1 g IV preoperatively, with a 7-10 day course* For seropositive recipients, valganciclovir 900 mg PO daily or ganciclovir 5 mg IV 5 times per week while CMV PCR positive* For seronegative recipients with seropositive donors, valganciclovir 900 mg PO daily for 6 months* or ganciclovir 5 mg IV 5 times per week or 1 g PO tid for 6 months Amphotericin B, itraconazole, or voriconazole for 1 year Trimethoprim-sulfamethoxazole prophylaxis 3 times per week For sulfa allergies, dapsone and inhaled pentamidine can be used
Empyema	<i>Staphylococcus aureus</i> <i>Streptococcus milleri</i> <i>Escherichia coli</i> <i>Pseudomonas</i> spp. <i>Haemophilus influenzae</i> <i>Klebsiella</i> spp. Anaerobes	Antibiotics should be based on culture and sensitivity from empyema; if not available, the following regimens are appropriate for 3 weeks Community acquired (all are acceptable periop abx) Cefuroxime 500 mg IV tid plus metronidazole 500 mg PO or 400 mg IV tid Penicillin 1 g qid plus metronidazole 500 mg PO or 400 mg IV tid Meropenem 1g tid plus metronidazole 500 mg PO or 400 mg IV tid Augmentin 875/125 mg PO tid Amoxicillin 1g PO tid plus metronidazole 400 mg PO tid Clindamycin 300 mg PO qid Hospital acquired (all are acceptable periop abx) Piperacillin-tazobactam 4.5g IV qid Ceftazidime 2 g IV tid Meropenem 1 g IV tid ± metronidazole 500 mg IV tid or 400 mg PO tid

*Based on empiric evidence gathered at Washington University in St. Louis, Mo.

clean-contaminated operative fields. Postoperative pneumonia was found in approximately 25% of patients undergoing lung resection in two different studies.⁴¹⁻⁴³ Radu and colleagues demonstrated that only 18% of the pathogens postoperatively isolated from patients with pneumonia were susceptible to first-generation cephalosporin.³ They recommend consideration of use of prophylactic antibiotics to cover gram-positive and gram-negative organisms.

Unfortunately, no clear data support this practice. The Surgical Care Improvement Project is a national program

sponsored by the Center for Medicare and Medicaid Services along with other health organizations (e.g., American Hospital Association, Centers for Disease Control and Prevention) to decrease the number of surgical complications.⁴⁴ Randomized trials showing an improved outcome with the use of antibiotics effective on gram-negative organisms are needed for surgeons in the United States to justify their practice. Surgical Care Improvement Project participation delineates the timing of prophylactic antibiotic administration (within 1 hour of surgical incision), the type of antibiotic (first-generation

cephalosporin with exceptions for allergies), and the duration of prophylactic antibiotic administration (limited to 24 hours or less for all surgeries except cardiac surgery; for cardiac surgery, 48 hours). If a patient is receiving antibiotics for a therapeutic reason, prophylactic antibiotic use does not apply.

Anticoagulation

Management of anticoagulation before thoracic surgery varies depending on the reason for anticoagulation, patient risk factors for bleeding or thrombosis, the urgency of the procedure, and which anticoagulant the patient is being given.⁴⁵⁻⁴⁸

For patients who are taking anticoagulation because of the risk of a thromboembolic event, risk stratification helps to guide management (Table 4-3).⁴⁸ When bridging with unfractionated or low-molecular-weight heparin (LMWH) or when continuing anticoagulation is the recommended strategy, assessment of the risk of bleeding perioperatively should be done.^{45,46} Some of the newer anticoagulants have a short half-life and do not require bridging. For patients taking anticoagulation for drug-eluting coronary artery stents, a period of 12 months before interrupting anticoagulation for elective surgery is recommended to prevent in-stent stenosis, which can have a mortality of 50%. For bare metal stents, a 6-week period of uninterrupted anticoagulation is recommended. If surgery is urgent or emergent, the risks of operation on anticoagulation versus in-stent stenosis should be weighed. If the risk of bleeding is thought to be such that anticoagulation needs to be stopped, treatment with antiplatelet medications with a short half-life such as tirofiban, cangrelor, or eptifibatide until several hours before surgery can be considered. If double antiplatelet treatment with aspirin and another antiplatelet medication such as clopidogrel is being used, continuation of the aspirin perioperatively is recommended.⁴⁸ More extensive discussion about managing the different types of target specific anticoagulants is not possible in this generalized

chapter. The references are helpful in describing specific patient situations.

Miscellaneous

Blood products are reserved for patients who have anemia preoperatively or a chance of significant blood loss during the surgical procedure. There are no studies that identify an unequivocal hemoglobin threshold for patient transfusion before or during surgery, but multiple studies have found that even critically ill patients will tolerate a hemoglobin of 7 mg/dL. An exception may be if the patient has acute ischemic cardiac disease.^{49,50} Previously, patients having elective major thoracic surgery were thought to be good candidates for the benefits of autologous blood donation, including decreased risk of infection, transfusion reaction, and immune modulation. However, the acceptance of lower patient hemoglobin levels, techniques leading to decreased intraoperative blood loss, and lack of cost effectiveness because of the processing and administration decreases the recommendation for autologous blood donation. The use of erythropoietic agents has been effective in eliminating or decreasing the amount of anemia in patients with cancer who have received chemotherapy or radiation therapy. Although preoperative or postoperative use of erythropoietin or darbepoetin is an attractive idea for thoracic oncology patients, increased mortality was found in patients who had not had neoadjuvant therapy.^{51,52} In addition, there are reports of increased risk of deep venous thrombosis in oncology patients who are given erythropoietic agents for anemia.⁵²

In the past, bowel preparation before esophageal resection was justified when colon interposition was planned.⁵³ Some surgeons also used bowel preparation for all patients undergoing esophagectomy, with gastric pull-up as a precaution should the stomach be found to be unusable during operation. Bowel preparation for colon resection has been studied by multiple randomized controlled trials and meta-analyses.⁵⁴ Evidence shows no

TABLE 4-3 Risk Stratification of Anticoagulated Patients for Further Thromboembolic Events

Risk Stratum	Indication for Anticoagulation		
	Atrial Fibrillation	Mechanical Heart Value	Venous Thromboembolic Disease
High >10% risk per annum	CHADS2 ≥ 5 Stroke or TIA within last 3 months Rheumatic valvular heart disease	Any mitral valve prosthesis Aortic valve prosthesis with tilting disc or caged ball Stroke or TIA in last 6 months	VTE within last 3 months Severe thrombophilia (deficiency in antithrombin, protein C or S)
Moderate 5-10% risk per annum	CHADS2 score of 3 or 4	Bileaflet aortic valve prosthesis with other stroke risk factors	Clot within last 3-12 months Recurrent VTE Active cancer
Low <5% risk per annum	CHADS2 score 2 or less and no previous stroke	Bileaflet aortic valve prosthesis	VTE > 12 months ago

CHADS2, 1 point each allocated for congestive heart failure, hypertension, age greater than 75 years, and diabetes mellitus, and 2 points for previous stroke; TIA, transient ischemic attack; VTE, venous thromboembolic disease.

benefit with mechanical bowel preparation regarding anastomotic leak or superficial surgical site infection for colon resection. Whether there is increased risk of anastomotic leak, deep or superficial surgical site infection for colon interposition after esophagectomy without bowel preparation has not been studied systematically. Histologic changes in colon mucosa were of a greater degree in patients who underwent mechanical bowel preparation, but it is not known whether these changes are clinically relevant.⁵⁵ Electrolyte and intravascular volume changes with bowel preparation may be magnified in esophageal surgery patients who have challenges with oral intake and hydration.

Surgery should never be delayed because of the unavailability of equipment. Hospitals often have equipment (laparoscopes, thoroscopes, video equipment, operative microscopes, lasers, vessel sealing and energy devices, ultrasonic devices, radiofrequency devices, cryoablation equipment, robots, specialized retractors) that is used by several different services. Such equipment should be reserved before the surgery to ensure that it is available and functioning properly. Perioperative management software allows for procedure scheduling, inventory maintenance, automatic supply reordering, and equipment conflict checking.

INTRAOPERATIVE CARE

Good communication with the anesthesiologist or anesthesiologist is essential. Airway management should be discussed beforehand if there are special circumstances. The entire operative team should know the plan of the operation including (1) anticipated anatomic outcome of the procedure, (2) position and planned position changes, (3) instrument, equipment, and medication needs (e.g., fluoroscopy devices, drainage tubes, local anesthetic), (4) general length of the operation, (5) possible unanticipated occurrences and treatment (e.g., bleeding), and (6) postoperative disposition (e.g., extubation versus postoperative ventilation, ward versus intensive care).

Ventilation

Single-lung ventilation during thoracotomy or thoracoscopy is accomplished by placing a double-lumen tube, bronchial blocker, endotracheal tube with in-line bronchial blocker, intermittent ventilation (for procedures of short duration) or, as a last resort, a single-lumen tube down the desired main-stem bronchus.^{56,57} Because of improvements in care, patients are living longer and selective lobar ventilation techniques may be necessary if previous lobectomy or pneumonectomy has been performed.⁵⁸ The use of lower intraoperative tidal volumes during single-lung ventilation has been shown to decrease the incidence of respiratory failure in lung resection patients.^{59,60} Increased peak inspiratory pressure, decreased oxygen saturation, and increased end-tidal CO₂ during the procedure without a known etiology from the surgical field lead to a differential diagnosis of retained secretions or blood, dislodgement of the endotracheal tube or blocker, or contralateral pneumothorax.

Stabilization may require reinflation of the operative-side lung if increased fraction of inspired O₂ (FiO₂) administration and oxygen flow and gentle bagging by the anesthesiologist do not improve the situation. Investigations and treatments include suctioning of obstructing blood or mucus, bronchoscopy and repositioning of single-lung ventilation equipment, or decompression of the contralateral pleural space of air.^{61,62}

Monitoring

Different operations require different levels of monitoring. ECG monitoring and continuous pulse oximetry measurements are necessary in all cases. An arterial line is placed if there is a need for multiple blood samples. Continuous arterial pressure monitoring is useful during procedures involving mediastinal dissection, such as transhiatal esophagectomy, to gauge cardiac or great vessel compression. Temperature monitoring by bladder temperature probe or esophageal temperature probe is necessary for major procedures (see [Body Temperature](#)).

Intravenous access should be appropriate for the invasiveness and potential blood loss of the procedure. Anticipated blood loss is rarely sufficient to justify the need for large-bore central lines. However, adequate access is necessary before the procedure starts, because the arms, chest, and groin are often inaccessible for line placement during an operation with a patient in the decubitus or prone position. In an emergency, a large-bore line can be placed in the operative field via the subclavian vein, superior vena cava, inferior vena cava, or azygous vein.

Body Temperature

Mild hypothermia has been shown to increase wound infection, blood loss and transfusion requirements, and cardiac events including ventricular tachycardia, cardiac arrest, and myocardial infarction.⁶³ Heat loss through thoracotomy, sternotomy, and laparotomy incisions can be lessened by keeping the room temperature greater than 21° C, using airway heating and humidification devices, covering portions of the patient not in the operative field, and using forced-air warming blankets. Warm saline lavage intrapleurally and intraperitoneally can also be performed. Intravenous fluid warmers are rarely necessary.⁶⁴

Positioning

Careful positioning of the patient is of utmost importance in the operating room. The surgeon needs to ensure adequate access for the planned operation and any potential counterincisions or chest wall resection. The use of muscle flaps often requires planning ahead to protect the vascular supply and to leave adequate skin coverage. Padding to prevent neuropathy includes the use of an axillary roll and head support to maintain neck alignment in the lateral decubitus position. Padding of all pressure points includes between the legs, the greater trochanter, fibular head, and lateral malleolus of the lower extremities. The dependent arm is supported on a padded board, the nondependent arm is slightly abducted,

and the shoulder and elbow are slightly flexed and rested on pillows or an arm support. Stability of the patient during the operation can be achieved using a deflatable beanbag, sand bags, laminectomy rolls, padded supports and posts, and security straps or tapes. The lithotomy position also requires careful positioning to prevent postoperative neuropathy, musculoskeletal strain to the lower spine, and skin and muscle ischemia.⁶⁵

Fluid Administration

Fluid administration during pulmonary resection is kept to a minimum. If pneumonectomy is planned, administration of 1 L of fluid during the intraoperative course has been advocated. During esophagectomy, additional fluid administration may be needed because of increased blood loss and third space fluid distribution. Clear communication between surgeon and anesthesiologist regarding blood loss, hemodynamic trends, and pressor and fluid administration during the operation is crucial.

Drainage

If the planned operation is scheduled to take longer than 3 hours or if an epidural catheter is used, a bladder catheter should be placed. Orogastric or nasogastric tube drainage is important for decompression during esophageal and gastric operations. The semirigid tube can be helpful for localization during reoperation or within radiated fields with abundant scar tissue or fibrous reaction.

The viscosity of the substance being drained dictates the size and shape necessary for adequate drainage of the pleural space. Smaller anterior tubes are used to drain air. Larger posterior tubes, including preformed 90-degree-angle tubes, are useful for dependent drainage of blood, pus, chyle, or exudative fluid along the diaphragm. One pleural tube is adequate for drainage after routine lobar resection if it is positioned posteriorly and to the apex of the pleural cavity to drain both fluid and air. If significant disruption of lung parenchyma is known or suggested, the use of more than one pleural drainage tube is prudent to prevent formation of subcutaneous emphysema and to improve the chance of pleural opposition. Additional chest tubes are used for empyema, hemothorax, or fistula drainage.⁶⁶⁻⁶⁸

The use of a drainage tube after pneumonectomy is controversial. Reasons cited for leaving a chest tube after pneumonectomy include the ability to monitor bleeding, to manipulate intrapleural pressure, and to adjust mediastinal shifting by instilling or removing air. The chest tube is removed intraoperatively after the patient is placed supine, in the recovery room, or on the first postoperative day. Many surgeons leave no drainage tube after pneumonectomy and encounter no increased morbidity.

A gastrostomy tube is useful if prolonged stomach drainage is needed. This can decrease the risk of aspiration that is theoretically present from having a tube traversing and stenting the upper esophagus open. A gastrostomy tube is more comfortable for the patient than an indwelling nasogastric tube. A jejunostomy tube is placed as access for nutrition and medicine administration if failure to thrive or a prolonged period of receiving

nothing by mouth (NPO) status is anticipated and intragastric feeding is not feasible.

If flaps are created, drains to prevent seroma formation are placed. If there is a possibility of leakage of the gastrointestinal tract, bronchopleural fistula, empyema, or chylothorax, good drainage can prevent systemic infection and can allow time for nutritional support and healing.

Specimen Management

The surgeon must also ensure that sample and specimen collection is performed properly. Careful labeling and delivery of frozen sections are of paramount importance in determining resection margins, resectability, and staging. Confirmation of adequate tissue sampling for diagnostic testing including immunohistologic and mutation testing is necessary as personalized medicine options increase. Intraoperative communication with the pathologist performing frozen section may be necessary before proceeding with the next portion of an operation. If possible, orienting the specimen and viewing the frozen section with the pathologist are recommended. A recent retrospective subset analysis of the data from the American College of Surgeons Oncology Group Z0060 trial of esophageal resection revealed that more accurate accounting and assignment of lymph node station occurs when surgeons separate and label lymph nodes for analysis than when the pathologist dissects, counts, and labels the nodes.⁶⁹ More lymph nodes were harvested during lung resection in a study that provided prelabeled containers for mediastinal and hilar lymph nodes.⁷⁰ Cultures for bacterial, fungal, viral, and acid-fast organisms need to be processed and collected in the correct specimen containers and mediums.

POSTOPERATIVE CARE

As in many other specialties, clinical pathways serve to improve the quality of care, and they have the added benefit of reducing cost.^{7,8,71,72} Almost all thoracic surgical patients can be transferred from the recovery room to a stepdown unit or surgical ward instead of to an intensive care unit. For thymectomy, segmentectomy, lobectomy, pneumonectomy, lung volume reduction, and esophagectomy patients, telemetry and continuous pulse oximetry measurements are recommended. The arterial line placed during surgery is transduced until the day after surgery.

Fluid Management

Fluid administration for lung resection patients must be determined on an individual basis. Controversies that have been studied without strong conclusion include (1) the use of goal-directed fluid therapy versus conventional fluid administration protocols, (2) liberal versus restricted fluid resuscitation, and (3) colloid versus crystalloid administration.⁷³⁻⁷⁶ The balance between providing enough fluid in the circulatory system for perfusion of end organs and microvasculature and overwhelming the

capillary filtration capacity leading to acute lung injury is not clear cut. A literature review of goal-directed fluid therapy by Wilms and colleagues revealed few studies with high or moderate quality evidence.⁷⁶ For patients not receiving mechanical ventilation, the high-quality study used central venous lactate levels to direct fluid resuscitation compared with a restrictive fluid strategy in patients having major gastrointestinal surgery for cancer. Patients with goal-directed therapy had fewer postoperative complications.⁷⁷ In patients receiving mechanical ventilation, goal-directed therapy included fluid administration or pressor and inotropic support to achieve a cardiac index of 2.5 as measured by a pulse contour arterial waveform monitor. This group had a shorter length of stay and a lower incidence of complications compared with patients receiving a conventional fluid administration protocol.⁷⁸ Restrictive fluid protocols are meant to decrease the incidence of acute lung injury, but they can contribute to acute kidney injury. There is also an increased incidence of acute kidney injury in patients who receive colloids intraoperatively, but this association has not been studied in depth. Chau and Slinger have published guidelines for fluid management perioperatively for lung and esophageal surgery⁷⁹:

1. Total positive fluid balance in the first 24 hours postoperatively should not exceed 20 mL/kg.
2. Crystalloid administration should be limited to less than 2 L intraoperatively and less than 3 L in the first 24 hours postoperatively.
3. Colloids should be used only to replace an equivalent volume of blood loss if blood is not required (maintain hemoglobin > 80 g); Maximum colloid volume = 1 L for an adult.
4. There is no third space loss.
5. Urine output greater than 0.5 mL/kg/h is unnecessary in the early postoperative period, unless the patient is at high risk of developing acute kidney injury
6. If increased tissue perfusion is needed postoperatively, appropriate invasive hemodynamic monitoring should be initiated to guide treatment with vasopressors, inotropes, or fluid administration.

Blood Administration

No hemoglobin level or hematocrit has been documented as being a threshold for recommending transfusion. Current clinical guidelines state that blood transfusion may be beneficial for patients with a hemoglobin less than or equal to 7 g/dL.⁴⁹ Although intuition argues that a higher hemoglobin level provides better oxygen delivery, the increased oxygen extraction by most organs and tissues when stressed negates the need for a higher hemoglobin level. This is not true for the heart, which extracts most of the oxygen delivered under nonstressed physiologic conditions and requires increases in blood flow to increase oxygen delivery with physiologic stress. For older patients with acute myocardial infarction and a hematocrit less than or equal to 30, decreased mortality was found with blood transfusion.⁸⁰

Perioperative blood transfusions have been shown to be associated with decreased survival after resection for

lung cancer.^{81,82} There have also been multiple retrospective series of decreased survival associated with perioperative blood transfusion after esophageal cancer resection.⁸³⁻⁸⁶

Medications

Each patient's preoperative medications should be reviewed before restarting them postoperatively. Often, antihypertensive medications need to be held for several doses until fluid shifting and intravascular volume equilibrium are attained to prevent continued hypotension. We recommend restarting β -blocker therapy as soon as possible after the operation to prevent rebound tachycardia from withdrawal. This therapy also decreases the occurrence of atrial fibrillation and of rapid ventricular response if postoperative atrial fibrillation occurs. Inadvertent discontinuation of home medications was shown for hospitalized patients, but especially for patients admitted to the intensive care unit.⁸⁷

Prolonged postoperative antibiotic administration to prevent surgical site infection has not been shown to be beneficial in multiple studies for pulmonary and esophageal resection.⁴⁰ The Surgical Care Improvement Project implemented in 2003 requires that prophylactic antibiotics for thoracic procedures be discontinued within 24 hours.⁴⁴ The use of a first-generation cephalosporin is recommended unless there is a concern for a high anaerobic burden in esophageal resection. In addition, prophylactic coverage for lung transplantation has specific recommendations because of the patient's immunosuppressed state (see [Table 4-2](#)).⁴⁰ Many patients suffer from nausea after general anesthesia or from postoperative pain medications. Antiemetics such as metoclopramide, ondansetron, promethazine, trimethobenzamide, and prochlorperazine can help. Stress ulcer prophylaxis is recommended for high-risk surgical patients only (see [Stress Ulceration and Gastritis](#), earlier).³⁶ Esophagectomy patients have a high risk of reflux.⁸⁸ H_2 -receptor blockers or proton pump inhibitors should be continued in patients who demonstrate reflux on barium swallow tests postoperatively, have symptoms of heartburn, or have a history of Barrett's disease.^{88,89} Some patients may have a bile reflux or a combination of bile and acid reflux and should be treated accordingly.⁹⁰ Vagotomized patients can benefit from the prokinetic effects of erythromycin or metoclopramide; however, erythromycin can cause gastrointestinal upset and metoclopramide can produce extrapyramidal symptoms.⁹¹

The use of low-molecular-weight heparin, low-dose unfractionated heparin, or sequential compression devices continues until the patient is reliably walking at least four times per day for patients with a low risk for deep venous thrombosis. For higher-risk patients, a combination of pharmacologic and mechanical prophylaxis should be used until the same ambulatory criteria are met. The use of LMWH for 4 weeks after hospital discharge in patients undergoing major abdominal, pelvic cancer surgery or with other high risk factors for VTE can reduce the incidence of asymptomatic deep venous thrombosis. There is no clear recommendation of whether extended prophylaxis should be applied to thoracic surgery patients

with cancer, but the American Society of Clinical Oncology supports a consideration of coverage for 4 weeks postoperatively (see [Box 4-2](#)).³⁵

Analgesia

Pain control is one of the most important aspects of postoperative care for thoracic surgery patients, and the amount of literature on this subject is beyond the scope of this chapter. Studies have shown the benefit of multimodal treatment for both acute and chronic pain after both thoracotomy and thoracoscopy. Recent articles by authors at Duke University review different classes of analgesics, how they are administered, and algorithms for decision making for postoperative pain control for thoracic surgery ([Figs. 4-1, 4-2, and 4-3](#) and [Table 4-4](#)).^{92,93}

Nutrition

Adequate nutrition is of paramount importance in the postoperative period. After lung resection, most patients can start consuming clear liquids or a regular diet the evening of surgery. A more cautious approach may be necessary if there is concern about a difficult airway, higher risk of respiratory failure, or aspiration. Nausea and vomiting are common after general anesthesia, and narcotic medications can magnify the problem. If liquids are tolerated, the patient's diet can be advanced starting

the day after surgery. After uneventful laparoscopic fundoplication, clear liquids can be given the evening of surgery. If a Collis gastroplasty or repair of inadvertent esophagotomy or gastrostomy was performed, NPO status and nasogastric tube aspiration may be desired for several days to prevent pressure on suture lines. These patients need to be counseled preoperatively and postoperatively about taking most of their fluid between meals, eating smaller portions more frequently during the day, and avoiding foods such as dry bread, raw vegetables, large chunks of meat, and foods and fluids that increase gas production in the immediate postoperative period. Providing patients at discharge with a list of eating tips and foods to avoid is recommended. Dysphagia caused by swelling of a complete fundoplication can occur after the operation; this can lead to an inability to advance the diet beyond liquids for several days or weeks.⁹⁴ If dysphagia persists past several weeks and the patient is losing weight, the need for dilation or investigation for a complication such as a slipped wrap, stricture, or previously undiagnosed motility disorder must be considered.^{94,95}

Oral intake after esophagectomy is usually started after a confirmatory test for leakage and blockage, such as a barium swallow test or grape juice test, is passed. Most surgeons wait 4 to 7 days postoperatively.^{71,96} Surgeon preference, problems encountered during the operation, and neoadjuvant therapy influence when oral intake is started. If the test results are favorable, clear liquids are started and the diet is advanced as tolerated.

The patient is counseled about expected changes in eating habits, dietary intake, jejunostomy tube feeding, and weight stabilization. Placement of a jejunostomy tube during esophagectomy allows enteral feedings to start 24 to 48 hours after operation. Tube feedings are generally started at a low rate, such as 20 mL/h, and advanced to a goal rate to provide total caloric and protein needs over the next 48 hours.⁷¹ If a jejunostomy tube is not placed, total parenteral nutrition administration until oral intake is tolerated can be considered.

Respiratory Therapy

The most common complications after thoracic surgery are related to the pulmonary system. Vigilant postoperative pulmonary care decreases the incidence of complications.^{97,98} Incentive spirometry and chest physiotherapy, including clapping, postural drainage, and vibratory therapy, aid in mobilizing mucous secretions and allowing patients to clear their own secretions.^{99,100} Cough can be stimulated and secretions can be suctioned by placing a soft suction catheter through the nose and into the trachea. Studies have advocated placement of a mini tracheostomy in high-risk patients and have shown favorable results in facilitating suctioning. There was no definitive evidence for decreased length of stay or mortality. Mini tracheostomy was associated with complications from placement, but most of these were minor and needed no further intervention.^{101,102} Ambulation is an excellent method of decreasing atelectasis. Nebulized albuterol is helpful in curtailing or preventing bronchospastic episodes. If a patient has had multiple

manipulations of the upper airway and there is concern about edema and stridor, intravenous and aerosolized steroids and aerosolized racemic epinephrine are effective in reducing edema.

Wound Care

Incision care is usually routine if the skin is closed. Open wounds historically are packed with gauze moistened with saline, dilute antibiotic solution, sodium hypochlorite (Dakin's) solution, acetic acid solution, or dilute Betadine solution. Newer dressings, including silicone-impregnated dressings, thin polyurethane films and foams, hydrocolloids, alginates, and hydrogels, are available, although there are no strong data to recommend the use of one over the other or gauze.¹⁰³ Vacuum dressings can be placed in clean or contaminated wounds and can speed the healing process.^{104–107} Open chests for bronchopleural fistula are packed with moistened gauze or negative pressure dressing to stimulate granulation and possible closure. If muscle or skin flaps are raised and there is the potential for seroma formation, drains can be left and binders or ace bandages can be considered. Depending on the muscle rotation used and the tautness of the closure, restriction of range of motion may be required for several days to prevent tension and dislodgement or compromise of flap vascular supply.

For wounds that are difficult to heal, such as those in previous radiation fields, hyperbaric oxygen therapy can be considered.¹⁰⁸ No randomized, blinded studies have shown definite benefit of hyperbaric oxygen therapy for wound healing except for osteoradionecrosis.

Management of Drainage Tubes

Placement and removal of chest tubes should be standardized by protocol after lung resection. Tubes are left in as long as any air leak remains, but recent studies indicate that earlier transition from water suction to water seal is not harmful and promotes quicker resolution of parenchymal air leakage. Fluid drainage of 300 to 400 mL or less per 24 hours is acceptable for chest tube removal after lung resection.^{66,71,109} Chest tube removal after pleurodesis for malignant pleural effusion has a stricter volume requirement, as these patients are known to have problems absorbing pleural fluid normally. Chest tube removal after drainage of chylothorax or empyema must be tailored to the particular patient's course. When

there is any concern about anastomotic leak in the chest or mediastinum after esophageal resection or tracheal reconstruction, tubes should be left until resolution of the leakage. Mediastinal tubes are left after median sternotomy is performed for removal of bilateral lung tumors, lung reduction surgery, or mediastinal mass resection.

Most surgeons leave a nasogastric tube after esophagectomy and for complicated benign esophageal operations. The tube is removed when drainage from the gastrointestinal tract is less than 300 to 500 mL per 24 hours and there is no concern of anastomotic leak.

Bladder catheters are placed for drainage and as a measure of adequate end-organ perfusion in patients having operations longer than 3 hours. Patients, especially older men, who have an epidural catheter often

TABLE 4-4 Consideration in Developing a Perioperative Pain Management Strategy*

Neuraxial Blockade or Continuous Paravertebral or Epidural Catheter	Intravenous Strategies or Single-Shot Peripheral Nerve Block
Medical conditions preclude the use of narcotics or predispose the patient to respiratory depression.	Clear contraindications to neuraxial blockade exist (e.g., allergy, patient refusal, infection, sepsis, recent thoracic spine surgery).
Anticoagulation is appropriately held or there is no predisposition for coagulopathy, or both.	Anticoagulation or coagulopathy is ongoing or highly likely.
The patient will have prolonged thoracotomy tubes and remain hospitalized for >24 hours.	Discharge will likely occur within 24 hours.
The patient will not be able to take oral pain medications for a few days.	The patient will be transitioned to oral pain medications quickly.
The patient has a chronic pain condition.	There is a minimal risk of conversion to open thoracotomy.
There is possible substantial lung resection, with a risk of conversion to open thoracotomy.	There is very little or no lung resection planned.

*The medical condition of the patient, surgical plan, and postoperative plan contribute to appropriate decision making when contemplating a comprehensive pain management strategy.

From Bottiger BA, Esper SA, Stafford-Smith M: Pain management strategies for thoracotomy and thoracic pain syndromes. *Semin Cardiothorac Vasc Anesth* 18:45–56, 2014.

have difficulty voiding and usually require the indwelling bladder catheter until the epidural is discontinued.

Physical Therapy

Exercise therapy after lung resection benefits patients by decreasing pulmonary complications, restoring mobility and independence, and decreasing the potential for deep venous thrombosis. Pulmonary rehabilitation is designed specifically to help patients clear secretions, strengthen respiratory muscles, and provide cardiopulmonary exercise.^{110,111} A patient who requires continuous chest tube suction can exercise on a stationary bicycle in the hospital room.

MANAGEMENT OF COMPLICATIONS

Early Complications

Respiratory Complications

Atelectasis and Pneumonia. The most common complication after a thoracic operation is respiratory failure. When complications are the result of atelectasis and retained secretions, treatment with aggressive pulmonary

toilet, postural drainage, incentive spirometry, nasotracheal suction, ambulation, and nebulized expectorant will help to clear the secretions. If pneumonia is suggested (fever, elevated and rising white blood cell count, purulent sputum production, no other source of infection), empiric treatment with a second-generation cephalosporin is justified, as radiographic changes of pneumonia may lag temporally.¹¹² The U.S. Food and Drug Administration (FDA) and the Infectious Disease Society of America advocate using bronchoscopy with lavage or protected brush for diagnosis of hospital acquired or ventilator associated pneumonia.¹¹³ Antibiotic therapy can be adjusted after culture results return. The worsening spiral of need for intubation can sometimes be avoided with bronchoscopy to remove thick tenacious secretions or retained blood clot from surgery. The benefits of mini tracheostomy have already been mentioned.^{101,102}

Prolonged Air Leak. A prolonged air leak is defined as one that lasts longer than 5 postoperative days. A useful review of different treatments for prolonged air leaks was recently published by Mueller and Marzluf.⁶⁸ If the patient has an emphysematous lung and the leak is small, several manipulations can be performed to encourage the leak to stop. If a pneumothorax or residual space still exists, placing the chest tube on higher suction can be tried, either by raising the water level in the suction chamber or by closing the air vent to the suction chamber and controlling the amount of suction pressure from the wall source. Pressures greater than 40 to 60 mm Hg are not recommended. Placement of another chest tube can help to fully reexpand the lung if the air leak is substantial. If the air leak and pleural space persist, pneumoperitoneum to raise the diaphragm and obliterate or lessen the space can be tried.¹¹⁴ Filling the space with viable tissue, such as muscle flaps or omentum, can be considered but is more invasive. If no residual space exists, placement of the chest tube to water seal or on a Heimlich valve can encourage the leak to seal. A blood patch can be attempted by injecting approximately 50 to 100 mL of the patient's own blood through the chest tube. This has been shown to be effective in both partially and fully expanded lungs, but it may need to be repeated several times and may increase the risk of empyema.¹¹⁴ Intrabronchial valves are approved by the FDA for prolonged air leak after lung resection and studies have shown improvement or resolution of leak in 45% to 50% of patients.^{115,116} Talc sclerosis through the chest tube can be performed, although this will cause pleural fusion, making it difficult to reenter the chest cavity in the future. If none of these methods work, the patient may need to be taken back to the operating room for leak closure. Air leak from the lung parenchyma can be troublesome because of friable lung tissue. Direct suturing with or without pledgets, use of fibrin sealants and glue,¹¹⁷⁻¹¹⁹ and stapling of a leak with pericardial or polytetrafluoroethylene strips can be attempted.

Pulmonary Edema. Pulmonary edema in lobectomy patients is serious but can usually be treated with diuresis. Postpneumonectomy pulmonary edema can be fatal. Aggressive respiratory care including intubation may

be necessary to manage a patient with postpneumonectomy pulmonary edema, which has a mortality rate of greater than 50%. Postpneumonectomy pulmonary edema should always be considered, and avoidance of excessive fluid administration is critical.^{75,79} Other maneuvers during surgery that have been recommended to avoid postpneumonectomy pulmonary edema include using tidal volumes of only 5 to 6 mL/kg to avoid barotrauma or volutrauma to the inflated lung,⁵⁹ avoidance of transfusion, and administration of steroids, although data are mainly from single-institution case series and retrospective studies.^{60,120} Although disruption of the lymphatic drainage resulting from lymphadenectomy has previously been implicated as a causative factor, data from the American College of Surgeons Oncology Group Z0030 trial did not support this finding.¹²¹ Controversy still exists regarding whether the laterality of the pneumonectomy affects the risk of postpneumonectomy pulmonary edema, and whether induction chemotherapy or chemoradiotherapy increases that risk.¹²²⁻¹²⁴

Urine output should be accepted at 0.5 mL/kg/h the night of surgery, and excess fluid administration should be avoided. Measures to keep pulmonary artery pressures low should be instituted. The patient should be given adequate FiO₂. Hypercarbia, pain that causes splinting, and atelectasis should be avoided. Routine administration of diuretic starting in the recovery room can be considered.

Acute Respiratory Distress Syndrome. Acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) are rare but potentially fatal complications after thoracic surgery. The reported frequency of each is 2% to 16%.⁷⁹ Aggressive support with reintubation if necessary and administration of positive end-expiratory pressure and adequate FiO₂ to support the patient while the lung recovers is important. No medication has been shown to improve the outcome of ARDS. Steroids can be tried for a short course.^{125,126} Prone position, nitric oxide, and high-frequency oscillating ventilation improve arterial oxygenation, but no randomized controlled studies have shown increased survival with these treatments.^{127,128} Other therapies reported include prostaglandins, extracorporeal membrane oxygenation, and liquid ventilation. Treatment of underlying pneumonia is necessary. Careful attention to other organ systems and nutritional support give the patient's lungs time to recover. The mortality rate for ARDS with no other organ system affected remains at 50% to 64%. If a patient displays signs of hypoxia and the etiologies just mentioned are not the cause, then pulmonary embolism, myocardial ischemia, arrhythmia, and heart failure need to be investigated.

Cardiac Complications

Myocardial Infarction. Myocardial infarction should be managed expediently with oxygen therapy, ECG monitoring, morphine, statins, and aspirin if bleeding is not a great concern.¹²⁹⁻¹³¹ Inotropic or pressor support may be needed in the immediate postoperative period. If the patient's blood pressure cannot be supported adequately

with medications, intra-aortic balloon pump placement should be considered. Patients with continuing ischemia and hemodynamic instability should be taken for cardiac catheterization to delineate significant stenosis and should undergo catheter-based therapy if indicated. Anti-coagulants such as heparin, ADP receptor antagonists (ticlopidine, clopidogrel, or prasugrel) or GIIb/IIIa platelet inhibitors (abciximab, eptifibatide, or tirofiban), or both, are recommended for unstable angina,¹³² but recent surgery and risk of bleeding may preclude their use. Adesanya and colleagues have recommended algorithms for both non-ST-segment elevation myocardial infarction and ST-segment elevation myocardial infarction (Figs. 4-4 and 4-5).¹³¹ The surgeon must exercise judgment regarding the risks and benefits of these drug interventions after surgery. Arrhythmias should be treated according to advanced cardiac life support protocol if the patient is hemodynamically unstable.

Atrial Fibrillation. The Society of Thoracic Surgeons published recommendations regarding prophylaxis and treatment of atrial fibrillation in general thoracic surgery patients in 2011.³² Electric cardioversion is the initial treatment of atrial fibrillation with hemodynamic compromise. Chemical cardioversion is the initial treatment for hemodynamically stable atrial fibrillation with intolerable symptoms. Recommended treatment of postoperative atrial fibrillation without hypotension is rate control for 24 hours. If conversion to sinus rhythm does not occur or paroxysmal atrial fibrillation continues past 24 hours, then chemical cardioversion is then tried. Anticoagulation is recommended based on a patient's risk of stroke if atrial fibrillation occurs for longer than 48 hours (Fig. 4-6).

Bleeding

Postoperative bleeding is monitored by chest tube output. Sudden occurrence of large-volume, bloody drainage requires immediate re-exploration to find and stop the source of bleeding. Less rapid bleeding of more than 100 mL/h for 2 consecutive hours is also excessive after thoracic surgery. If the patient has been taking aspirin or other antiplatelet agents such as clopidogrel, prasugrel, or ticagrelor, and if surgery was emergent or required before the known washout period (5 to 10 days depending on the medication), then platelet dysfunction must be considered.¹³² Unfortunately, there is no reversal agent or antidote for the newer antiplatelet drugs. Platelet transfusion is ineffective if therapeutic levels of the active metabolite of the medication are present. Patients who are treated with newer anticoagulants to prevent or treat thrombovascular disease, including dabigatran, rivaroxaban, and apixaban, will have elevated prothrombin time and partial thromboplastin time, but there is no good correlation between test results and amount of drug activity. In life-threatening bleeding, prothrombin complex concentrate in combination with activated factor VII can be given to attempt to reverse the effects of these medications, but the risk of thromboembolic events will be increased.^{133,134} If a coagulopathy exists, goal directed expeditious administration of lysine analogs,

FIGURE 4-4 ■ Suggested algorithm for management of perioperative non-ST-segment elevation myocardial infarction. *ACE*, Angiotensin-converting enzyme; *HMG-CoA*, 3-hydroxy-3-methylglutaryl-coenzyme A; *IABP*, intra-aortic balloon pump; *NSTEMI*, non-ST-segment elevation myocardial infarction. (From Adesanya AO, de Lemos JA, Greilich NB, et al: Management of perioperative myocardial infarction in noncardiac surgical patients. *Chest* 130:584–596, 2006.)

prothrombin, DDAVP, cryoprecipitate, activated factor VII, and prothrombin complex concentrate, fresh frozen plasma¹³⁵ and keeping the patient normothermic⁶³ may help slow or stop bleeding. If bleeding persists after correction of deficient factors, exploration for a bleeding source should be performed. If coagulopathy and bleeding have been controlled but hematoma causes significant mediastinal or lung compression, then re-exploration is necessary. Transfusion of packed red blood cells should be considered, depending on the patient's hemoglobin level and hemodynamic condition.

Late Complications

Pulmonary Complications

Bronchopleural Fistula. If air is leaking from the bronchial stump, adequate chest tube drainage to prevent or drain empyema is necessary. Bronchoscopy should be performed to examine the stump and to identify the area of leak. If the hole cannot be visualized, slow administration of saline via the bronchoscope into the stump can reveal bubbles or drainage of the saline through a small hole. If the stump is not the area of leak, sequential bronchial examination and occlusion with balloon tipped

catheters within the lumen of segmental or lobar bronchi can be performed. By visualizing decreased air leakage from the chest tube with occlusion of certain airways, gross localization can be performed. Multidetector computed tomographic scanning with intravenous contrast using thin slice (1.25–5 mm) acquisition allows (1) visualization of air bubbles adjacent to the leaking bronchus or parenchymal rent if present, (2) coronal and sagittal views in addition to the usual axial cuts to allow better three-dimensional localization of bronchopleural fistula, and (3) construction of virtual bronchoscopy images.¹³⁶ Treatment can consist of operative closure or endobronchial closure. Multiple biological glues, adhesives, irritants, stents, vascular plugs or occluders, and coils have been reported to seal small bronchopleural fistulas successfully in case reports.¹³⁶ Special catheters and deployment devices are necessary to administer the treatments through the bronchoscope to the site of the leak. Reoperation for closure of the leaking bronchial stump may be needed. The standard approach of Zaheer and colleagues includes trimming a long bronchial stump or debriding a poorly vascularized stump and then covering the stump with an extraskelatal muscle flap (e.g., the serratus anterior or latissimus dorsi).¹³⁷ If vascularized tissue is inadequate to close a bronchopleural fistula, the extraskelatal muscle is

FIGURE 4-5 ■ Suggested algorithm for management of perioperative ST-segment elevation myocardial infarction (STEMI). CABG, Coronary artery bypass grafting; IABP, intra-aortic balloon pump; IV, intravenous; PCI, percutaneous coronary intervention. (From Adesanya AO, de Lemos JA, Greilich NB, et al: Management of perioperative myocardial infarction in noncardiac surgical patients. *Chest* 130:584–596, 2006.)

sewn circumferentially to the stump for closure. Wide drainage to prevent unilateral empyema and contralateral soiling should be performed; this can include thoracotomy and performing open packing in the operating room every several days or under conscious sedation in the patient's room for several days to weeks until the cavity is clean. An Eloesser flap can be performed to facilitate open packing. Once clean, dilute antibiotic solution is instilled, and airtight chest closure is performed. Mobilization of the remaining chest wall musculature and additional rib resection may be necessary to allow chest wall closure without tension; this alleviates a lifetime of packing an open chest, which predisposes to failure to thrive and recurrent bronchitis and pneumonia, and limits the patient's daily activities and lifestyle. If the chest wall is too contracted or rigid to allow airtight closure, an Eloesser flap can be used with packing or vacuum assist dressing to allow cleansing and possible granulation and closure of bronchopleural fistula.^{106,138} An alternative approach involves pleural irrigation with antibiotic solution, intravenous antibiotics, and nutritional support. Gharagozloo and colleagues recommend an antibiotic solution composed of gentamicin (80 mg/L), neomycin (500 mg/L), and polymyxin B (100 mg/L), and an airtight thoracotomy closure without drainage should be instituted when pleural cultures are negative.¹³⁹ Ng and coworkers used antibiotic irrigation for 2 weeks, tailored to the organism grown in pleural culture.¹⁴⁰

A persistent pleural space after lung resection can be prevented with a pleural tent if it is anticipated at the time of surgery. The apical portion of the parietal pleura is

dissected from the chest wall and tacked to a lower intercostal muscle. The chest tube(s) are placed within the pleural tent. The pleura adhere to the surface of the remaining lung and help seal over any leaking areas, and they decrease the volume of space that the remaining lung needs to fill. Either the space on top of the pleural tent in the apex fills with serous fluid, as it does after a pneumonectomy, or the lung expands to fill the whole space. This change is also aided by elevation of the hemidiaphragm. Encouraging the diaphragm to rise can be accomplished with pneumoperitoneum. Air can be instilled across the diaphragm with a needle during thoracoscopy/thoracotomy or periumbilically at a later time. Care must be taken not to damage the liver, spleen, or stomach.⁶⁸ Injection of the phrenic nerve with local anesthetic causes a temporary paralysis that also encourages the hemidiaphragm to rise. No respiratory compromise resulting from this practice has been reported. Filling of a residual space with healthy living tissue such as muscle or omentum can also be performed, although this is generally not done during resection because such extreme measures are unlikely to be needed. Lastly, thoracoplasty can be performed but is rarely used.¹⁴¹

Bronchovascular Fistula. Bronchovascular fistula is a rare complication that needs to be considered after bronchoplastic procedures are performed for lung cancer or lung transplantation.¹⁴²⁻¹⁴⁴ Fistulas sometimes first appear with a herald bleed, followed by massive hemoptysis. Salvage after a major bleed is rare, and the best treatment is to decrease the chance of fistula formation by placing

FIGURE 4-6 ■ Suggested algorithm for management of postoperative atrial fibrillation. AF, Atrial fibrillation; ASA, acetylsalicylic acid (aspirin); COPD, chronic obstructive pulmonary disease; ILD, interstitial lung disease; INR, international normalized ratio; PO, by mouth. (From Fernando HC, Jaklitsch MT, Walsh GL, et al: The society of thoracic surgeons practice guideline on the prophylaxis and management of atrial fibrillation associated with general thoracic surgery: executive summary. *Ann Thorac Surg* 92:1144–1152, 2011.)

vascularized tissue, such as intercostal or extraskelatal muscle, pleura, pericardium, or omentum, between the pulmonary artery and the sutured bronchus. If massive hemoptysis occurs, an attempt at placing a double-lumen tube to isolate the nonaffected lung from blood spillage may allow enough time for the chest to be opened and the bleeding controlled. Unfortunately, salvage is rare and the patient dies of suffocation more often than exsanguination.

Postpneumonectomy Syndrome. Postpneumonectomy syndrome is torsion or compression of the trachea, bronchus, esophagus, or pulmonary vasculature caused by mediastinal shift after pneumonectomy. Placement of a tissue expander or a saline breast prosthesis into the post-pneumonectomy space is reported to reverse some of the mediastinal shift and its consequences.^{145,146}

Wound Infection and Empyema. Wound infection after chest surgery is rare. The wound should be opened to allow adequate drainage. If the patient also has an empyema, tube drainage of the pleural cavity through a separate site can be attempted along with opening of the wound. If the infection extends into the pleural space, it

is better to take the patient back to the operating room for a thorough drainage, irrigation, débridement, and decortication if the space is not well drained by chest tube. Strong consideration should be given to leaving the skin open. Wound vacuum dressings have been successful in pleural spaces even with remaining lung parenchyma and gross soilage.¹⁰⁶ If the cause of empyema is a bronchopleural fistula, the infection should be cleared, and then definitive treatment of the bronchopleural fistula is undertaken as mentioned earlier.

Post-thoracotomy Pain. Chronic post-thoracotomy pain syndrome remains a devastating and debilitating result after thoracotomy.^{92,93} It is pain that occurs along a thoracotomy scar at least 2 months after surgery, and its incidence is 44% to 67%. Minimally invasive thoracic surgery continues to increase and although it has been shown to cause less pain than thoracotomy, some patients still suffer from chronic pain.¹⁴⁷⁻¹⁴⁹ Treatment can involve several modalities, including medications, behavioral techniques, and procedures. Combinations of medication include nonsteroidal anti-inflammatory drugs, tricyclic antidepressants, anticonvulsants such as gabapentin, opioids, and lidocaine patches. Behavioral techniques

such as biofeedback, hypnosis, and relaxation techniques may be offered. Procedural treatments include intercostal nerve block, paravertebral block, intrapleural local anesthetic, radiofrequency ablation, cryoablation, and transcutaneous electrical nerve stimulation. Referral to a pain specialty clinic with a team consisting of anesthesiologist, nutritionist, physical therapist, psychiatrist or psychologist, occupational therapist, and pharmacist is recommended for comprehensive care.

Complications after Esophageal Surgery

Many of the complications encountered after lung resection, particularly the respiratory complications, also occur after esophageal surgery. A recent meta-analysis compared perioperative outcomes of minimally invasive esophagectomy to hybrid minimally invasive esophagectomy and open esophagectomy.¹⁵⁰ Minimally invasive esophagectomy showed decreased overall morbidity, blood loss, hospital length of stay, and pulmonary complications. There was no difference on overall mortality and anastomotic leak. The mortality of esophagectomy has declined since 1999, but it continues to be higher than of other cancer resections, including lung resection, pancreatectomy, and cystectomy indicating continuing need for improvement in patient selection, preoperative optimization, intraoperative technique, and postoperative care whether performed by minimally invasive or open technique.¹⁵¹ The incidence of pulmonary complications after esophagectomy ranges from 11% to 32%.¹⁵² Patients are at high risk of aspiration after esophagectomy, especially if they have recurrent laryngeal nerve injury.¹⁵³ Aspiration precautions including elevation of the head of the bed at all times, the chin tuck maneuver, eating and drinking only out of bed and sitting at 90 degrees, smaller but more frequent meals, with the last meal being several hours before sleep, and education by speech pathologists and nutritionists about food choices, mechanics of eating, and concentration during eating are of paramount importance.

Dysphagia

Difficulty swallowing is one of the most frequent complications after any esophageal surgery. At times, it is self-limited and is caused by recent surgery.^{94,95,153-155} However, persistent dysphagia after fundoplication, myotomy, or esophageal resection should be investigated. Workup usually includes barium swallow, motility studies, esophagogastroduodenoscopy, or a combination of these. Anatomic or functional abnormalities such as too tight a fundoplication, slipped fundoplication, recurrent herniation, motility disorder, and ulceration may be found. Treatment depends on the cause of the dysphagia and ranges from simple observation to dilation, medical treatment, or reoperation.⁹¹

Anastomotic Leak

Anastomotic leak or perforation occurs because of multiple factors including ischemia, inflammation, distention of conduit and pressure at suture lines, poor nutrition,

anastomotic tension, or technical problems.^{156,157} The location and size of the leak determine the treatment. If a neck anastomosis is leaking, the neck wound is opened to allow drainage and healing over time. Stricture can form and require dilation, but it is usually not incapacitating. Some surgeons advocate NPO status during that time to reduce the amount of pressure and fluid draining past the hole, whereas others believe that oral intake serves to dilute bacterial rich saliva and allow dilation of the lumen, which promotes passage down the true lumen for cervical anastomotic leaks that are easily drained from the neck incision without mediastinitis. Antibiotics are not necessary if the leak is adequately drained. If the leak is more than a quarter of the circumference of the anastomosis, debriding unhealthy tissue and primary reclosure of the anastomosis should be considered.

If the anastomosis is within the chest, a leak may be contained in the space around the conduit, into the pleural cavity, or into the mediastinum. A leak into the pleural cavity should be drained with chest tubes. The patient is placed on NPO status. Intravenous antibiotics are administered unless the patient has no fever or leukocytosis and there is a well-formed drainage tract to the tube. Drainage into the mediastinum can be fatal if it is not evacuated. If the patient is toxic, reoperation for adequate drainage should be performed to prevent mediastinitis and sepsis. If there is adequate healthy tissue after débridement and the patient is not toxic at that time, reanastomosis can be considered. If ischemia or soiling with unhealthy tissue exists, wide débridement with esophageal diversion may be needed. If a significant amount of the stomach needs to be resected, the hiatus should be closed to prevent herniation. For small, persistent anastomotic leaks, both removable polyester-silicone stents and expandable covered metallic stents have been successful in excluding the leak and allowing tissues time to heal without continued soiling.¹⁵⁷

Stricture

Stricture after esophageal surgery can occur at an anastomosis; at the diaphragmatic hiatus; above, below, or within a fundoplication; at the pylorus; or at the site of previous myotomy. Stricture can be secondary to technical problems, ischemia, leak, ulceration, or reflux, and it can be multifactorial.¹⁵⁶ Most strictures that occur after recent esophageal surgery can be treated with either balloon or bougie dilation.¹⁵⁷ Multiple dilations may be necessary in the early period after surgery. With the passage of time, the frequency of dilation for each patient decreases until it is no longer necessary. If the anastomosis was performed for esophageal cancer, biopsy to exclude persistent or recurrent cancer should be performed.¹⁵⁶ A few patients need repeated dilation on a long-term basis, and some are able to dilate themselves at home after being taught. If a stricture remains refractory, temporary stenting may be beneficial.^{91,153,154}

Conduit Ischemia

Continuous knowledge of the position of the gastroepiploic arteries as the greater curvature dissection is

performed prevents inadvertent ligation or damage to the main vascular pedicle used during gastric pull-up. Leaving the right gastric artery intact provides a dual blood supply to ensure adequate blood flow to the stomach as it is transposed into the chest or neck. Careful handling of the gastric tube during passage into the chest or neck and prevention of twisting, torqueing, or folding is of paramount importance. The distal tip of the conduit should be pink when positioned and before anastomosis. Bleeding at the gastrostomy site created for stapler insertion or hand-sewn anastomosis and healthy-appearing mucosa should be seen. Conduit ischemia of colon interposition can be avoided by assessment of the blood supply before surgery if the patient has had previous gastric or colonic operations. An angiogram of the mesenteric arteries may be desired before the colon is used as a conduit to ensure patency of the marginal artery. Supercharging has also been used to provide increased perfusion to colonic or jejunal conduits when used as primary conduit or for reconstruction after esophageal diversion.^{158,159} Conduit ischemia can be difficult to diagnose postoperatively, but symptoms and signs of infection or an inflammatory response without a known source should raise the level of suspicion. Unless diagnosed and treated early, conduit ischemia leads to further morbidity or mortality. If a significant portion of the conduit is ischemic or the surrounding tissues are unhealthy from inflammation, takedown of the anastomosis, creation of an esophagostomy, and return of the gastric remnant to the peritoneal cavity with closure of the hiatus is recommended.^{153,160}

Recurrent Laryngeal Nerve Damage

Damage to the recurrent laryngeal nerve is more common after transhiatal resection or three-hole resection because of the dissection and retraction in the neck where the recurrent nerves are exposed in the tracheoesophageal groove. Recurrent laryngeal nerve damage not only causes hoarseness; it also compounds discoordination of swallowing and increased risk of aspiration in patients already at risk for these problems because of absence of the lower esophageal sphincter and decreased motility due to division of the vagus nerves. The incidence of this complication can be lowered by careful avoidance of metal retractors deep in the neck wound and visualization of the nerve. If vocal cord paralysis is evident after esophagectomy, assessment for aspiration by modified barium swallow or fiberoptic endoscopic evaluation, or both, by a speech pathologist is recommended before oral intake. If aspiration is present, the patient may need to be kept on NPO status with nutrition maintained by tube feeding until vocal cord medialization is performed to decrease the risk of aspiration and to increase the ability of the patient to make an effective cough.^{153,160}

Chylothorax

The incidence of chylothorax is 0.4% to 0.8% after esophagectomy. It usually manifests several days after the operation when tube feeding or oral intake is started.

Drainage of moderate to large volumes of milky whitish fluid from the chest tube or with thoracentesis is usually diagnostic. Analysis of the fluid for lipids with a triglyceride-to-cholesterol ratio of greater than 1 or a triglyceride level greater than 110 g/dL confirms the diagnosis. The thoracic duct may be injured while mobilizing the lower thoracic esophagus, and leakage is usually into the right chest. Conservative measures such as a low-fat or medium-chain triglyceride diet can be tried, but if the drainage does not decrease after several days, full NPO status and total parenteral nutrition should be instituted. Chyle contains abundant proteins, and patients can become nutritionally depleted quickly. Octreotide infusion or subcutaneous administration has been successful in treating chylothorax in case reports.^{153,160} Percutaneous embolization of the thoracic duct or cisterna chyli also has good results.¹⁶¹ Some surgeons prefer not to wait more than 5 days before taking the patient back to the operating room for thoracic duct ligation just above the right hemidiaphragm. This can be done thoracoscopically or with a thoracotomy. Lymphangiography is generally not helpful in localizing the leak, and most radiologists are not trained in this method anymore. Feeding the patient cream or a fat-laden food several hours before surgery can elucidate the leaking portion of the duct. The leaking point is ligated and the duct is ligated at multiple other points just above the diaphragm. Chest tube output should decrease drastically, and the patient can be fed again.

Functional Problems

Dumping syndrome occurs because of high osmotic load from the stomach into the small bowel because of a lack of antral control after the vagus nerves are divided and pyloromyotomy or pyloroplasty is performed.^{91,160} This can occur approximately 20 minutes or several hours after a meal. Dietary adjustments such as decreasing the intake of foods with refined sugars and eating smaller, more frequent meals without a large amount of fluid are helpful in improving symptoms. Fiber intake and acarbose, which interferes with carbohydrate absorption, may help. More severe symptoms can be treated by subcutaneous octreotide.¹⁶² Delayed gastric emptying also occurs after esophagectomy because of division of the vagus nerves and decreased stomach motility. Although in the past most surgeons performed a drainage procedure at the pylorus to prevent gastric outlet obstruction, there is no conclusive evidence that this is necessary.^{163,164} Some surgeons are now adopting balloon dilation, botulinum toxin injection, or no intervention of the pylorus. At times, dilation of the pylorus or the anastomosis will need to be performed.

Gas-bloat syndrome can occur after fundoplication. Patients complain of feeling full of gas and being unable to belch for relief. Dietary changes to decrease the amount of gas-producing foods, avoidance of carbonated beverages, eating slower to decrease air swallowing, prokinetic drugs, and the passage of time usually relieve the symptoms of this syndrome. There is some suggestion that a partial fundoplication leads to less gas-bloat syndrome than total fundoplication.¹⁵⁵

Reflux

Gastroesophageal reflux is common after esophagectomy and gastric pull-up. The lower portion of the stomach remains subjected to positive intraperitoneal pressure while negative intrathoracic pressure exerts an influence on the upper portion of the stomach without a lower esophageal sphincter. Patients with a history of Barrett's esophagus or symptoms or findings of esophagitis after gastric pull-up should receive antireflux medication. Patients should be counseled to eat and drink in the upright position and remain upright for at least 2 hours after eating. The head of the bed should be elevated 30 degrees, or they should sleep on a foam wedge to avoid nighttime reflux and aspiration. Avoiding damage to the recurrent laryngeal nerves helps to diminish the risk of aspiration when reflux occurs.^{91,155}

Miscellaneous

Myasthenic crisis is respiratory muscle weakness causing respiratory failure after thymectomy for myasthenia gravis. Positive-pressure mask breathing or ventilation should be used to support the patient through the acute crisis. Pyridostigmine is usually not effective during crisis. If steroids and intravenous immune globulin do not provide enough symptom relief, plasmapheresis may be needed to clear the circulating antibodies.¹⁶⁵ Cholinergic crisis results from overtreatment with anticholinesterase medications. The patient may have symptoms related to muscarinic receptor activity (e.g., excessive salivation, sweating, abdominal cramping, urinary urgency, bradycardia). Nicotinic receptor symptoms include fasciculations and muscle weakness. Cholinergic crisis does not respond to neostigmine. Treatment includes respiratory support, atropine, and cessation of anticholinesterase medications.¹⁶⁶

Cerebrospinal fluid leak is a rare complication seen when tumor is resected near the spine. The assistance of a neurosurgeon is recommended, and primary closure should be done if possible. Coverage with fat or pleura can also be used to help seal the leak. Other treatments involve placing lumbar drains to decrease the amount of cerebrospinal fluid pressure to allow the leak to seal on its own. The symptoms include leakage of clear fluid and development of intractable headache after resection close to the spine or involving the vertebrae.¹⁶⁷

DISCHARGE PLANNING

Discharge needs should be assessed preoperatively or soon after the surgery. The surgeon can often predict what services will be needed, based on the patient's preoperative health and family support network. A recent study used American College of Surgeons National Surgical Quality Improvement Program (NSQIP) data to develop a short tool to estimate the likelihood of discharge to another facility instead of to home.¹⁶⁸ The patient and family are made active participants in plans for timely discharge. Team meetings with social workers, nurses, physical therapists, and respiratory therapists

about each patient's needs are helpful for planning. Occupational therapists and physical medicine physicians can indicate what level of rehabilitation patients will need after discharge. A list of medications for home use, their purpose, and dosage is reviewed with the patient and the caregivers before discharge, including the changes from preoperative medications. Activity level and home-going exercises should be reviewed, and patients should demonstrate them to the therapist before leaving to ensure that they are being performed correctly. Driving of motor vehicles is limited while the patient is taking narcotic medications. If thoracoscopy for lung resection is performed, there are no limitations of activity save for those that affect intrathoracic pressure such as scuba diving. Patients who had minimally invasive foregut surgery involving the esophageal hiatus should limit heavy lifting to allow healing and prevent suture rupture from strong Valsalva. There is no prohibition for showering or stair climbing.

Outpatient pulmonary rehabilitation or physical therapy programs should be contacted and established before discharge. The goal is to return the patient to a normal lifestyle as soon as possible. Visiting nurses can be invaluable in helping patients once home, for vital sign checks, administration of antibiotics or blood draws, tube care, and wound care. They allow patients to be discharged who need help for only several minutes a day. The follow-up appointment and any laboratory studies or radiology studies that need to be obtained before the appointment should be arranged before the patient's discharge. Appropriate contact telephone numbers should be provided should the patient have difficulty after discharge.

Complications

Endoscopy, especially fiberoptic endoscopy, has revolutionized nearly all theaters of medicine in terms of diagnosis and therapeutic intervention.¹ This revolution is particularly true for thoracic surgery, where bronchoscopy and esophagoscopy are essential modalities in the diagnosis, approach, and treatment of tracheal, bronchial, and alimentary tract pathology. As the technology of optics, endoscope instrumentation, and appurtenances such as endoscopic ultrasound and yttrium-aluminum-garnet (YAG) laser have evolved, so have the indications and capabilities of the skilled endoscopist. Although many clinicians may perform endoscopy, thoracic surgeons in particular should be adept and pioneering with these procedures, because new endoscopic technology will continue to enable all aspects of minimally invasive thoracic surgery.

ESOPHAGOSCOPY

In 1868, Kussmaul intubated a sword swallower's stomach via the esophagus with a 13-mm hollow metal tube. This maneuver proved that the oral cavity, esophagus, and stomach could be simultaneously intubated with one rigid instrument. Mikulicz added one crucial aspect to the tube—a distal light to illuminate the esophagus and stomach—and he was able to visualize gastric motility and view probable malignancies. The fiberoptic endoscope was introduced in 1958. This instrument allowed more patient comfort as well as greater therapeutic possibilities in the distal stomach and proximal small

intestine. Although the scope itself has not changed greatly, the adjunctive instruments have dramatically changed the way many disease states can be treated.²

Indications

For the thoracic surgeon, dysphasia and odynophagia are two of the most common indications for esophageal endoscopy (Box 5-1). Others include reflux, an abnormal esophagogram, trauma, screening, or staging of gastrointestinal or adjacent masses including tracheoesophageal fistulas. Upper gastrointestinal bleeding is another common indication for endoscopy, which has become the first line in management of this clinical scenario. Likewise, esophagoscopy can be a useful tool in evaluating and treating patients with known or suspected complications following surgery of the foregut.

Dysphagia can arise from a number of pathologic processes. Many causes can be distinguished with a careful history that records the duration and persistence of symptoms and accompanying constitutional complaints. Endoscopy allows the surgeon to distinguish between malignant and benign causes of dysphagia with direct endoscopic visualization and pathologic sampling, thereby guiding therapy.

Reflux is another indication for upper endoscopy. The thoracic surgeon searches for any long-term sequelae associated with chronic gastroesophageal reflux disease, such as Barrett esophagus. Esophagoscopy is crucial in the surveillance of known Barrett esophagus because of the link with the development of adenocarcinoma. Many

BOX 5-1 Indications for Upper Endoscopy

- Persistent nausea and vomiting
- Upper abdominal pain, heartburn, or acid reflux symptoms (i.e., an acid or burning sensation in the throat or chest)
- Gastrointestinal bleeding (vomiting blood or blood found in the stool)
- Difficulty swallowing; food or liquids get stuck in the esophagus
- Abnormal or unclear findings on an upper gastrointestinal radiograph
- Removal of a foreign body
- Follow-up on previously found polyps (growths), tumors, or ulcers

From the American Society for Gastrointestinal Endoscopy: Appropriate use of gastrointestinal endoscopy. Gastrointest Endosc 52:831–837, 2000.

support recommendations for surveillance at 3- to 5-year intervals, but its efficacy in reducing death from esophageal cancer has not been firmly established.^{3,4}

Upper gastrointestinal bleeding is another indication for endoscopy, and the procedure is often used therapeutically, as with bleeding esophageal varices—a difficult problem that can be palliated endoscopically with banding or sclerotherapy.

The most common reason for a thoracic surgeon to perform upper endoscopy is to visualize and biopsy esophageal and proximal stomach masses. Biopsy has a sensitivity of 66% to 96% in esophageal cancers.^{5,6} Seven to 10 biopsies are usually taken throughout the area of the lesion, or randomly in the setting of Barrett esophagitis. For lesions with a tight stricture, the surgeon can use a small-diameter scope, and brushings have been shown to increase the yield of tissue in such cases.^{6,7} After foregut surgery, endoscopy is also useful in the management of postoperative complications for both therapeutic and diagnostic purposes. The role of endoscopic ultrasound in the diagnosis and staging of esophageal disease will be discussed later.

Upper endoscopy can also play a role in the assessment of other mediastinal masses and malignancies that cause esophageal obstructive symptoms. Endoscopy can reveal whether the lesion is causing mass effect or actual erosion through the wall of the esophagus, possibly resulting in a fistula.

Upper endoscopy is also important for investigating trauma—blunt, penetrating, or caustic—and for foreign body retrieval. When using endoscopy to remove foreign bodies lodged in the esophagus, the surgeon should be alert to the potential for intraesophageal lesions, which may be responsible for the failure of material to pass through. The thoracic surgeon is frequently asked to document and manage iatrogenic trauma to the esophagus via instrumentation. Although the esophagogram is the mainstay for the diagnosis of perforation, the usefulness of endoscopy for the diagnosis and documentation of the extent of injury should not be underestimated. Cases of esophageal perforation have been reportedly managed with endoscopic techniques—primarily stenting. Most experience comes from extreme cases when

patients either are too acutely ill for attempts at repair or have minimal systemic derangement. In these highly select cases, outcomes have been favorable.⁸

Corrosive ingestion is another indication for early (within 36 hours) endoscopic inspection, which can help to identify transmural involvement and subsequent development of strictures.⁹

Preprocedure

Most endoscopies can be performed on an outpatient basis with conscious sedation. Patients should receive nothing by mouth (NPO) after midnight for a morning examination, and those with obstructive symptoms should be administered a clear liquid diet for 24 to 48 hours before the examination. When the patient arrives, a peripheral intravenous line and electrocardiograph (ECG) leads should be placed. Because the sedatives can cause respiratory depression, continuous ECG and pulse oximetry monitoring is performed, and blood pressure measurements are obtained frequently during the procedure. Once the monitors are in place, sedation is given to ensure that the patient is comfortable and cooperative. Local anesthesia minimizes the degree of conscious sedation required.

Flexible Esophagoscopy

Technique

The most common position for examination of the outpatient is the left lateral decubitus, with the head flexed. A bite block is placed into the mouth to protect the endoscope from the teeth, and the endoscope is introduced under direct vision. The epiglottis and larynx should be seen and advanced over until the piriform sinuses become apparent. If the vocal cords are visualized, any abnormalities should be documented. Gentle pressure is applied against the upper esophageal sphincter at the cricopharyngeus, and the patient is instructed to swallow, which usually results in successful and atraumatic esophageal intubation.

The four normal endoluminal landmarks in the esophagus are as follows: (1) the upper esophageal sphincter at the cricopharyngeus, 15 to 18 cm from the incisors; (2) the aortic arch, usually evident as an indentation on the left anterolateral wall; (3) the left atrium, seen in the distal esophagus as wavelike pulsations of the anterior wall of the esophagus; and (4) the lower esophageal sphincter, which in reality is just a physiologic sphincter and which can be demonstrated by asking the patient to perform a Valsalva maneuver and noting the pinching off of the lumen. The esophagus is generally easy to assess, and very little air insufflation is required to view its entire course.

Once the gastroesophageal junction has been passed, it is easy to advance into the stomach. The stomach should be insufflated with enough air to flatten out the rugae and allow visualization of the entire mucosal surface. The pylorus is visualized, and the scope can be advanced beyond the sphincter when it is relaxed. The duodenum should be inspected to the third portion.

Once this has been performed satisfactorily, the scope should be withdrawn slowly to see any potentially missed pathology. In the stomach, retroflexion of the scope allows visualization of the body and cardia of the stomach as well as evaluation of the distal extent of disease for lesions at the level of the gastroesophageal junction. Insufflated air should be suctioned before leaving the confines of the stomach. During the withdrawal, the scope should be pulled back slowly to assess the esophagus carefully. Next, the endoscope is removed and monitoring of the patient continues.

Complications

Complications are rare after flexible upper endoscopy. Morbidity rates of 0.13% to 0.092% include cardiovascular reactions to premedication, perforation, and bleeding. Most complications occur within the setting of instrumentation and risk must be placed in context of the underlying pathology or indications for the procedure. Mortality rates are exceedingly rare, quoted at 0.018% to 0.004%.^{10,11}

Rigid Esophagoscopy

Rigid esophagoscopy is a rarely used modality, usually reserved for three instances: trauma, removal of impacted food, and removal of foreign bodies. Rigid esophagoscopes can accommodate larger graspers than the working channel of a standard flexible esophagoscope and do not require insufflation. The scope is held in the examiner's right hand while the left hand keeps the mouth open with the left thumb protecting the upper dentition. During the insertion of the scope, the head is initially held forward, in the "sniffing position" used for tracheal intubation. Once the cricopharyngeus is passed, the head is extended to eliminate the angle of the mouth and the pharynx. The scope can then be advanced carefully throughout the length of the esophagus and proximal stomach. Manipulating the head and cervical spine at the areas of narrowing allows less traumatic passage.

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound (EUS), for which a small ultrasonic transducer is attached to the end of the endoscope, is a relatively new adjunctive procedure that has expanded the examination of the esophagus and the periesophageal tissues. It is never an initial procedure, but it is indicated when a previous esophagoscopy has been performed and pathology has been located and evaluated. Indications for esophageal ultrasound range from benign to malignant esophageal disease and include evaluation of periesophageal pathology, usually bronchogenic carcinoma (Box 5-2). The most common indication for EUS is the evaluation of esophageal malignancy. The stage of the lesion, as defined by the depth of invasion and nodal involvement, is the best predictor of surgical resection and therefore possible cure.

The normal esophagus has five distinct layers of alternating echogenicity. The first layer, which is the most

BOX 5-2 Indications for Endoscopic Ultrasound

ESOPHAGUS

- Staging esophageal cancer
- Evaluating esophageal submucosal lesions
- Evaluation of high-grade dysplasia arising in Barrett esophagus
- Evaluation of response of esophageal cancer after chemotherapy
- Differentiating achalasia from pseudoachalasia
- Evaluation for periesophageal varices

MEDIASTINUM

- Nodal staging of lung cancer
- Evaluation of selected mediastinal masses
- Evaluating posterior mediastinal lymphadenopathy

hyperechoic (white), is the epithelium and lamina propria. The second layer, which is hypoechoic (black), is the muscularis mucosa. The third layer, which is again hyperechoic, is the submucosa. The fourth hypoechoic layer is the muscularis propria. The last layer, the paraesophageal tissue, is thick and hyperechoic. Tumor (T) stage is determined by which layers are invaded. Accumulating data suggest that EUS is the most accurate imaging modality for staging esophageal malignancies. When EUS results are compared with surgical pathology specimens, EUS demonstrates a preoperative sensitivity of 80% to 92%.¹² The main advantage of EUS over conventional radiology (computed tomography [CT]) is the differentiation of the T stage, especially between the T3 and T4 stages, which can influence the decision to offer the option of surgery to the patient.¹³ The accuracy of EUS for staging of regional lymph node metastasis has been in the range of 70% to 80%, which is better than that of CT or magnetic resonance imaging.¹³ The regional lymph nodes (N) stage and distant metastasis (M) stage are determined in part by biopsy results, which depend on their being seen on examination. Accurate staging is now achieved by fine-needle aspiration biopsy, which can be performed on nodal tissue or organ tissues in direct contact with the esophageal wall. After examination of the three different TNM tissues, the patient can be preoperatively staged. EUS is becoming the standard of care in the evaluation of esophageal malignancies. It can also be a useful adjunct for access to the lower mediastinal lymph node stations for staging for primary lung cancer and other malignancies with concern for mediastinal involvement.

TRACHEOBRONCHOSCOPY

Gustav Killian, a German laryngologist, is credited with first use of bronchoscopy in 1897. He used a rigid scope to remove a foreign body (bone) from the right mainstem bronchus of a patient. The modern era of flexible bronchoscopy arrived at about the same time as esophagoscopy, once the problem of flexible fiber orientation was solved. Ikeda was the first to report the use of a flexible fiberoptic bronchoscope in a patient.¹⁴ New

modalities such as ultrasound, cautery, fine-needle biopsy, YAG laser, and autofluorescence techniques have been coupled with more elegant instrumentation and digital optics to produce the scopes of today. Some of these new modalities have yet to find their particular niche in the modern paradigm.

Tracheobronchoscopy can be performed with a flexible or a rigid instrument, or a combination of the two, depending on the indication and the disease encountered. Flexible bronchoscopy allows the thoracic surgeon not only to diagnose, stage, plan surgical approach, and monitor therapy, but also to palliate, temporize, and alleviate a myriad of thoracic pathologies. Rigid bronchoscopy is used less, and it requires more care, but it is nonetheless indispensable in certain situations. Endobronchial ultrasound (EBUS) is a relatively new modality with growing applications in the diagnosis and staging of primary lung cancer.

Indications

Flexible bronchoscopy can be used for definitive diagnosis of infectious, malignant, and traumatic tracheobronchial diseases (Box 5-3). Pulmonary toilet, endoluminal débridement, endotracheal intubation and extubation, percutaneous tracheostomy placement, and treatment of atelectasis are also elegantly accomplished with the flexible bronchoscope. Perhaps the most important use for the thoracic surgeon, however, is in the staging and assessment of disease before surgery, and in particular, the surgical staging of a primary lung malignancy. After preliminary evaluations with CT and positron emission tomography suggest a resectable lesion, the surgeon surveys the tracheobronchial tree for evidence and extent of endoluminal disease before proceeding with mediastinoscopy and ultimately formal resection. Not only is this evaluation essential from a surgical oncologic perspective, but it is also invaluable in terms of defining anatomy and planning resection. If a video-assisted thoracoscopic approach is to be used for resection, the ability to recognize abnormal bronchial anatomy by endoscopy allows resection to be conducted more safely and can influence anesthetic decisions regarding lung isolation strategies. Furthermore, assessing the cancer's endoluminal involvement can help to determine whether lobectomy, sleeve lobectomy, pneumonectomy, or carinal resection should be used.

Direct forceps biopsy, fine-needle aspiration (FNA), endoluminal brush biopsy, and washings are all methods of obtaining tissue that can be performed with flexible bronchoscopy. Mediastinal lymph nodes can be sampled by ultrasound-guided FNA. Although this is inferior, in terms of sensitivity and specificity, to mediastinoscopy as a staging modality, it is often a useful adjunct to cancer staging.

For patients with acute pneumonia in the intensive care setting, flexible bronchoscopy is indispensable for acquiring samples to culture for microbial speciation and antibiotic sensitivities. Routine washings are performed by administering sterile saline through the irrigation port of the bronchoscope, usually in 10-mL volumes. This fluid is then aspirated into a sterile specimen and sent to

BOX 5-3

Indications for Flexible Bronchoscopy

DIAGNOSTIC

- Lung cancer
- Positive sputum cytology
- Paralyzed vocal cord
- Localized wheeze
- Unexplained pleural effusion
- Hemoptysis
- Cough
- Diffuse interstitial infiltrates
- Immunocompromised state
- Ventilator-associated pneumonia
- Endotracheal tube position or patency
- Atelectasis
- Tracheoesophageal fistula
- Acute inhalation injury
- Bronchography

THERAPEUTIC

- Mucous plug
- Acute lobar collapse
- Difficult intubation
- Foreign body removal
- Hemoptysis
- Brachytherapy
- Laser ablation
- Electrocautery
- Stent placement with pulmonary infiltrates
- Balloon dilation

the laboratory for cytology and culturing. The washing may also be performed by bronchoalveolar lavage (BAL), in which larger volumes of saline are used to reach more terminal bronchioles. The advantage of BAL is that more cellular and noncellular material is retrieved for examination. After the flexible scope is wedged into the fourth or fifth terminal bronchioles, sterile saline is instilled in increments of 50 mL, aiming for a total of 150 to 200 mL, and then aspirated into a specimen trap. The first aspirations contain mostly airway cells, whereas later aspirations can contain alveolar samples. The specimens are handled in the same manner as routine washings, but the absolute cell counts obtained can be useful in the workup of inflammatory, allergic, and autoimmune lung disease. Certain infections, such as atypical tuberculosis, histoplasmosis, and those caused by *Mycobacterium tuberculosis*, *Pneumocystis carinii*, and *Mycoplasma* spp., are readily diagnosed by BAL.¹⁵

In intubated patients with copious secretions, endoluminal stents, mucous plugs or clots, and purulent pneumonias, regular bronchoscopy can assist with pulmonary toilet and diagnosis. Toilet bronchoscopy is often particularly helpful for patients with impaired mucus clearance, such as active smokers, those with chronic obstructive pulmonary disease or cystic fibrosis, and those who have undergone pulmonary resection or lung transplantation.

Bronchopleural fistula and traumatic tracheobronchial injury are also readily diagnosed by flexible bronchoscopy. Suspicion of either entity should prompt evaluation

by endoscopy to definitively and expeditiously rule out such a contingency.

In addition to being used for diagnosis, the flexible bronchoscope is also invaluable for intubation and extubation in precarious airway situations. Small-caliber fiberoptic scopes can be used to define obscure or complex oropharyngeal anatomy, intubate the trachea, and serve as a guide wire over which an endotracheal tube can be passed securely. In these patients, the scope can also aid in withdrawal of the endotracheal tube and then a temporary trial of extubation, providing the ability for a rapid and secure reintubation should the extubation fail.

Percutaneous tracheostomy, the technique of choice for tracheostomy placement in many intensive care units, is considerably safer with the use of flexible bronchoscopy to ensure proper needle, guidewire, dilator, and finally tracheostomy tube placement.

Endobronchial Ultrasound

EBUS uses a small ultrasound probe fitted through a flexible bronchoscope port, and it enhances visualization of the soft tissue of the mediastinum adjacent to the bronchial lumen. Both radial probes, which provide a 360-degree image of the airway and surrounding structures, and convex probes, which provide a 90-degree image, can be used. Soft tissue characteristics of pulmonary nodules, lymph nodes, and tumors can be delineated. This imaging can effectively guide transbronchial FNA to sample pulmonary nodules, tumors, or lymph nodes with greater safety and accuracy. Although primarily used for determining the N staging component of the non-small cell type of lung cancer, EBUS can also help to define the T component if the tumor is adjacent to or approaching the tracheal or bronchial lumen. EBUS allows access to superior and anterior mediastinal lymph nodes, and it can be combined with EUS access of inferior and posterior mediastinal lymph nodes to allow a more comprehensive sampling of the mediastinum. An advantage of EBUS is that it is a minimally invasive office procedure. Disadvantages include the need for several passes of the needle for increased diagnostic accuracy, limited availability, and access to rapid on-site cytologic examination. In terms of pathologic assessment for metastasis, FNA can be performed only with a 22-gauge needle; therefore, comprehensive staging is subject to sampling error. In the setting of highly suggestive mediastinal lymph nodes (enlargement on CT or increased metabolic activity on positron emission tomography), EBUS with FNA has reported sensitivities of 82% to 88%.^{16,17} The negative predictive value is low (60%); therefore, a negative EBUS examination result for mediastinal lymph node staging should always be followed by surgical mediastinoscopy, which remains the gold standard for N staging in lung cancer.^{18,19}

Navigational Bronchoscopy

By coupling high-resolution CT imaging with electromagnetic guidance of bronchoscope-delivered biopsy instruments, investigators have sampled more peripheral lung lesions that are inaccessible to conventional

methods.^{20,21} Lesions that are beyond tertiary bronchioles, and some beyond secondary, are too small to accommodate even small biopsy bronchoscopes. Guiding brushes or biopsy forceps into the distal bronchial tree is assisted somewhat with fluoroscopy, but this is still an almost blind procedure. Real-time, three-dimensional CT has been coupled to an electromagnetic navigational system (the superDimension bronchus system, superDimension, Herzliya, Israel)²⁰ that can virtually guide the bronchoscopist in sampling peripheral lung lesions. The procedure is a two-stage process with preprocedure planning and the procedure itself. The patient is placed on an electromagnetic board that can define the biopsy probe location in three dimensions and in real time. The probe's location is then coupled with its anatomic location in a three-dimensional, superimposed CT scan map of the patient. The biopsy device is then virtually guided to the sample site. Thus far, only feasibility studies¹⁵ have been performed; they show promise for this new technique as a means to sample peripheral lung lesions heretofore accessible only by surgery or CT-guided biopsy. Barriers to more widespread use include cost, specialized imaging, technical training required, and lack of direct comparison studies between navigational bronchoscopy and transthoracic CT-guided biopsy techniques.

Flexible Bronchoscopy

Technique

Most diagnostic bronchoscopy procedures should be performed with an awake patient and with topical anesthesia. When the patient is already intubated or needs general anesthesia for a combined procedure, local anesthesia is not needed. In the outpatient setting, the room should be equipped with monitors for pulse, blood pressure, and continuous pulse oximetry readings.

The size and caliber of the bronchoscope usually depends on the size of the patient and the need for larger working channels if endobronchial intervention is anticipated. The field of vision is generally 80 degrees, and the angle of deflection is usually 160 to 180 degrees. The light source is connected with a flexible cord, and the transmission of light and the resultant resolution are based on the number of flexible fiberoptic bundles. More light, however, results in higher-caliber scopes.

Essential equipment consists of the bronchoscope, a light source, a camera, biopsy tools, suction and irrigation, and a sputum trap. After informed consent has been obtained, the patient is positioned in a seated position so that topical anesthesia (gargled and spray lidocaine solution) and gentle sedation (intravenous midazolam) can be administered. Either a transnasal or a transoral approach can be used in the awake patient, with the latter being better tolerated. The transnasal approach in the awake patient has the advantage of allowing visualization of the nasal and upper airway and better stabilization of the scope.²² Manipulation of the scope begins with the user holding the handle of the scope in the dominant hand, controlling the shaft with the nondominant hand, and viewing with an eyepiece or a video screen. By manipulating the thumb lever at the scope handle and rotating a

taut scope shaft, the tip of the scope can be pointed in all directions. After insertion, the trachea is examined, searching for luminal irregularities. The first landmark is the carina, which should be a sharp bifurcation; any fullness in this area should alert the operator to subcarinal adenopathy or mass involvement of the proximal airway. Orientation is maintained by noting that the membranous trachea is always posterior. The operator then systematically examines all airways to the segmental and subsegmental bronchus level. Digital photography and video are both superb for documenting any disease encountered. This documentation is a useful reference for monitoring disease progression at subsequent procedures or when planning a surgical resection. All pathology should be documented with detailed written descriptions or pictures of the actual findings. Depending on the findings, the surgeon can investigate further with washings, lavage, brushings, and biopsy. Once extracted, the bronchoscope should be irrigated with sterile solution and sent for disinfection.

Complications

In experienced hands, flexible bronchoscopy is safe. The complication rate reflects the patient's preexisting disease and degree of intervention and therapy. Injudicious suctioning can cause damage to the endobronchial lumen and bleeding, and careless advancement of the scope can disrupt anastomoses and bronchial stump staple lines, dislodge broncholiths or clots, and even cause perforation,²³ all with disastrous consequences. Patients with a history of asthma or bronchospasm should be approached with particular caution, and with appropriate medications at hand. Intubated patients in extremis who manifest refractory hypoxia, elevated airway pressure, or cardiac arrhythmias should undergo bronchoscopy with extreme prejudice only.

Most large series on flexible bronchoscopy cite morbidity rates of 0.05% to 0.1% and a mortality rate of approximately 0.01%.²⁴ Morbidity is generally defined as respiratory compromise, symptomatic bradycardia, hypotension, syncope, or arrhythmias. Although manipulation of the instrument may be responsible for some of these manifestations, morbidity is usually related to the administration of and reactivity to the premedication and local anesthesia. Transbronchial FNA, with ultrasound guidance, has a pneumothorax rate of approximately 5% in most series; this is minor in most cases. Significant hemorrhage is also a risk with FNA, because major vessels (e.g., the pulmonary artery) can be punctured inadvertently, but the risk is greatly reduced by Doppler ultrasound.

Rigid Bronchoscopy

Rigid bronchoscopy should be mastered by all thoracic surgeons because it can be lifesaving in dire situations; it is a diagnostic and therapeutic intervention availed by our specialty alone. Massive hemoptysis, foreign body removal, tracheobronchial obstruction by benign or malignant stricture, airway stenting and dilation, and laser therapy are best approached with the rigid

bronchoscope. This procedure is performed less often than flexible bronchoscopy, because general anesthesia is required, and because it is difficult to become facile with the instrument. However, despite its greater technical difficulty, the rigid scope has several distinct advantages over the flexible scope. First, the rigid scope allows accurate definition of central airway lesions; with it, the surgeon can palliate these lesions. Second, the rigid scope allows ventilation through its lumen, providing direct control of the airway in the setting of airway disease. Third, the instruments, including suctioning tools, that can be used with the rigid scope are larger and thus more effective than the small instruments developed for use with the flexible scope. Therefore, the rigid scope is more helpful in managing hemoptysis and in foreign body removal.

Massive hemoptysis, defined as 600 mL of blood over 24 hours, mandates urgent rigid bronchoscopy. Once bronchoscopy is introduced, the airway is controlled. The point of bleeding is then investigated, and intervention is planned and attempted. The use of a proximal eyepiece allows visualization without compromising ventilation. Rigid bronchoscopy does not obviate the use of the flexible scope; flexible bronchoscopy can be performed through the lumen of the rigid scope to further the examination and possible intervention of the airway disease.

Foreign body extraction is usually technically easier through the rigid scope because of the large caliber of the instrument. Again, airway control is established, and the foreign body can be extracted with forceps, or on some occasions with a balloon catheter should the offending mass be lodged in the airway. Rigid bronchoscopy is also a critical evaluation tool in the management of patients with malignant airway obstruction. In this setting, it provides not only diagnostic information in terms of anatomy and pathologic sampling for consideration of surgical resection, but it also provides excellent palliation of symptoms in the setting of unresectable disease.

Shortcomings of the rigid method include poor visualization of the terminal bronchi, the inability to perform instrumentation and suction with excellent vision, and the need for general anesthesia.

Technique

Elective rigid bronchoscopy is performed on an intubated, paralyzed, and sedated patient. Often, a laryngeal mask airway is used to secure the airway before the intubation. Communication with the anesthesia team concerning the plan and expectations of the procedure is essential to ensuring smooth transition between the rigid scope and the endotracheal tube and laryngeal mask airway. Adequate sedation and paralysis and optimal oxygenation via the rigid scope are essential. A shoulder roll is placed under the patient to allow maximal extension of the neck. The rigid scope is introduced with the thumb of the surgeon's nondominant hand braced on the upper incisors and, as when positioning a laryngoscope blade, the scope is advanced around the tongue until the arytenoids and cords are visible. The scope is then delicately insinuated between the cords, a maneuver that is

facilitated by the appropriate angle of insertion and by rotating the scope 90 degrees as it is passed between the cords. Once beyond the cords, the scope is rotated back so that its longer lip is placed posteriorly. The side port attachment is then fitted to allow oxygenation via the scope throughout the procedure. At this point, biopsy, foreign body removal, balloon tamponade, YAG laser, and stenting procedures can be executed. A myriad of specialized endobronchial instruments accompany most rigid bronchoscope sets. Should the need arise, modern laparoscopic instruments can be useful for difficult foreign body or biopsy extractions. Passage of the flexible bronchoscope, or videoscope, down the rigid scope provides more magnified viewing of the trachea and bronchi. Measurements for stenting and dilation procedures, as well as for tracheal resection, can be performed accurately with the dual scope configuration. The scope is then withdrawn carefully under direct vision. It is of utmost importance that the scope be stabilized by the operator at all times.

Complications

Although rare, complications of bronchoscopy do occur. Preprocedure steps include workup of any comorbid cardiac disease or coagulopathy, and careful consideration of the underlying pathology and the possible consequences of bronchoscopic intervention. An essential step to any procedure is the informed consent, which entails educating the patient about the possible complications and the probable effects on the patient.

The risks of rigid bronchoscopy are much more significant than those of flexible bronchoscopy, with the largest series quoting a morbidity of 5.1% and with 1.1% being construed as major.²⁵ The main reason for the increased risk encountered with rigid bronchoscopy is the greater likelihood that patients selected for this procedure have more complex pathologies and thus require more complex interventional procedures. The increased morbidity also reflects the increased use of the rigid scope for palliative procedures, and the increased risk of subsequent complications.

The first recorded bronchoscopic intervention is attributed to Gustav Killian, who in 1897 used an esophagoscope to remove a piece of pork bone from a patient’s right mainstem bronchus.¹ A few decades later, Chevalier Jackson, now known as the father of endoscopy, became instrumental in the advancement of the field of rigid endoscopy of both the airway and esophagus.¹ Advancements in endoscopic technology have led to safer and more effective alternatives to surgery in non-operative candidates. This chapter focuses on endoscopic bronchial and esophageal interventions, including photodynamic therapy, radiofrequency ablation, laser ablation, brachytherapy, and stenting. Evolving endoscopic procedures for benign esophageal diseases (achalasia, Zenker diverticulum, and gastroesophageal reflux) are also discussed.

PHOTODYNAMIC THERAPY

Definition and Mechanism of Action

The principle of photodynamic therapy (PDT) lies in the preferential accumulation and subsequent activation of a photosensitizing agent in target cells, that when activated by light of a specific spectrum, results in selective tissue destruction. Photosensitizers used in thoracic surgery include the most commonly used purified hematoporphyrin derivatives (porfimer sodium [Photofrin]), chlorines (temoporphin or *m*-tetrahydroxyphenyl chlorin [*m*-THPC]), and 5-aminolevulinic acid (5-ALA). Each molecule is activated at an optimal wavelength of light absorption (630 nm for porfimer sodium and 5-ALA and 652 nm for *m*-THPC).

Although photosensitizers accumulate in all cells of the body, higher concentrations are retained within neoplastic cells and their interstitium within 1 to 4 days. Although the mechanism remains unclear, increased cellular proliferation, altered lymphatic drainage, and neovascularization are hypothesized to be responsible for the increased accumulation seen in neoplastic tissues. When laser light of the appropriate wavelength is delivered to neoplastic cells harboring the photosensitizer, it triggers a series of events culminating in cell destruction. The individual cells are bombarded with photons of a wavelength specific to the photosensitizer being used. The absorbed energy then acts as a catalyst in the formation of highly reactive oxygen species (e.g., superoxide anions, peroxide anions, singlet oxygen) whose primary cellular targets of photodamage include cellular membranes, amino acids, and nucleosides. It is important to remember that all cells will absorb some of the currently available photosensitizers; thus, surrounding normal tissue will be damaged to some degree and can limit the effectiveness of phototherapy.

Technique

The first step in PDT is the administration of the photosensitizer. Porfimer sodium (1.5 to 2.0 mg/kg) and *m*-THPC (0.075 mg/kg) are injected intravenously; 5-ALA (30–60 mg/kg) is given orally. Despite the benefit of being able to administer orally, increased tumor specificity and shorter duration of skin photosensitivity, 5-ALA has yet to gain widespread clinical acceptance.^{2,3} At the current oral dose, 5-ALA PDT accumulates preferentially in the mucosa and results in a more shallow tissue injury with necrosis only to a depth of 1 mm. Higher 5-ALA doses are avoided because of its increased side effects (e.g., malaise, nausea, vomiting, alopecia, transient elevation of liver enzymes). On the other hand, *m*-THPC is 100 times more photoactive than porfimer sodium, and it has a shorter elimination half-life; this results in deeper penetration and necrosis. As a result, *m*-THPC is typically reserved for use in malignant lesions that penetrate into submucosa or deeper.

The most commonly used photosensitizer is porfimer sodium, which has a depth of penetration of approximately 5 mm. It can be given in the outpatient setting, 1 to 4 days before endoscopic light application. It is most commonly used for endoluminal tumors of the airway and the esophagus, but other applications include anorectal, dermatologic, gastric, and hepatobiliary. Its short-term side effects include chest pain, odynophagia, and fever. Education of the patient is essential to minimize complications related to photosensitivity. Patients are instructed to avoid all sunlight and bright indoor light exposure for 30 days. Patients remain photosensitive for a period of 4 to 8 weeks, after which they can be gradually reexposed to sunlight.

Our preference has been to use conscious sedation and flexible endoscopy in most cases. A cylindrical diffuser fiber is used to deliver light therapy to the tumor. The sizes used are 1, 2.5, and 5 cm (Fig. 6-1). Choice of fiber length is based on technical ability to expose the tumor maximally to the light and to minimize the surrounding normal tissue

FIGURE 6-1 ■ Photodynamic therapy diffuser fibers: 2.5 and 5 cm.

exposure. The diffuser fiber is placed alongside the tumor. If this is not possible because of occlusion of the lumen, the tumor can be impaled with the probe. Caution should be exercised if impalement of the tumor is attempted, because without viewing and defining the length of tumor obstruction and determining where and whether patent distal lumen begins it can be somewhat risky. Multiple light illumination cycles may be needed, depending on the length of the tumor relative to the length of the probe. The diffuser must be positioned to minimize light delivery to normal tissues. Endoscopy is repeated at 48 hours and sometimes a third time after an additional 48 hours. During the repeated endoscopic procedures, necrotic debris is removed by irrigation and suction. Usually, further light treatments are delivered to the tumor at the time of repeated endoscopy.

In many cases, PDT can be performed in the outpatient setting; however, caution should be exercised in treating nearly obstructing lesions of the esophagus or central airways, because perioperative edema and necrotic tissue can temporarily worsen obstruction, leading to dyspnea or, in the case of esophageal obstruction, initial worsening of the dysphagia.

Contraindications

Contraindications to PDT are few. Patients suffering from porphyria or those who are allergic to porphyrins cannot receive porfimer sodium. PDT is contraindicated in the presence of an esophagorespiratory fistula or in tumors eroding into a major blood vessel. PDT is not recommended for the treatment of obstruction caused by extraluminal compression, since the effectiveness is limited because of an inability to expose the tumor to the light activation. Caution should be used in treating patients with underlying renal or hepatic dysfunction.

Lung Cancer

Curative Intent

Photodynamic therapy has been used in an investigational setting for the treatment of lung cancer since 1980.

It is currently approved as a treatment option for centrally located early stage 0 (TisN0M0) and stage 1 (T1N0M0) lung cancer. These small central tumors are rare, although some centers with active early screening programs, such as sputum cytology or light-induced fluorescence bronchoscopy, encounter these tumors more frequently.⁴ The results of PDT for these small lesions should be compared with the results of surgical resection. The central location of these tumors may necessitate complex airway reconstructions. PDT may be a suitable alternative to resection in patients who are not surgical candidates or as an adjunct in decreasing tumor burden prior to surgical resection. There are few central airway tumors that are discovered at a curable stage, because most of these early-stage, centrally located endobronchial lesions often go undetected by radiologic studies. In addition, only about 10% of all non-small cell lung cancer tumors occur in a central location. Superficially spreading tumors (<3 cm²) and small endobronchial tumors (<1 cm²) are reasonable targets for PDT. Initial complete response can be expected in 65% (<3 cm²) to 85% (<1 cm²) of superficial cancers and in 30% (>0.5 cm nodule) to 92% (<0.5 cm nodule) of nodular cancers.^{5,6} Long-term response rates (i.e., >1 year) vary between 30% and 80%.^{5,9} At 5 years of follow-up, complete response rates of up to 29% to 66% have been reported depending upon the exact size, location, and stage of the lesion.^{5,7}

In a study of 21 operative candidates treated initially with two courses of PDT, 52% (11 of 21) were free of tumor at 1 year.⁷ Curative PDT failed in the remaining 48% (10 of 21), and they were offered surgery; 8 consented. Of the 11 responders, 9 (9 of 21; 43%) did not require surgery (mean follow-up, 68 months), and 2 were operated on for a second primary lung cancer. It is noteworthy that of the patients who eventually underwent resection, 30% were found to have N1 disease, supporting the role of resection when possible. Our policy has been to reserve curative PDT for patients with significant comorbid factors or those who refuse pulmonary resection. In this group of patients, PDT is an excellent option, with an expected 1-year survival of up to 80%.¹⁰ In our initial experience of treating 10 superficial cancers, a complete response was seen in 70% at a follow-up of 30 months.⁸ In other prospective series, 80% to 93% of nonsurgical candidates were alive at 5 years of follow-up.^{5,11}

Palliative Intent

Resection should continue to be the main therapy for early-stage non-small cell lung cancer, because only a relatively small number of patients will have curable central tumors that are suitable for PDT with curative intent. A much larger group of patients with advanced, inoperable, or obstructive central lung cancers may benefit from palliative PDT. In this situation, the therapeutic goal should be symptomatic relief and preservation of quality of life and functional status. Patients most notably find improvement in obstructive symptoms, such as dyspnea or hemoptysis, yet the need for strict photosensitivity precautions should be considered in patients with limited survival.

A cohort of 175 patients with endobronchial non-small cell lung cancer treated with PDT was observed prospectively for a period of 14 years.¹¹ Most patients had squamous cell carcinoma (89.3%), and treatment by conventional modalities, including chemotherapy, radiotherapy, laser ablation, and surgery, had failed in 73.1%. The mean number of treatments was 2.8 per patient. After multivariate analysis, stage was found to have the most significant effect on survival. Poor performance status (i.e., Karnofsky performance status < 50) negatively affected outcome in advanced-stage tumors (IIIA-IV). However, patients with a low Karnofsky performance status (<50) secondary to pulmonary symptoms still derived benefit from PDT. Prolonged survival (12 to 37 months) was observed in 66% of stage IIIA-IV patients with poor performance. The median survival for the entire group was 7 months. Of the 44 patients with stage IV disease, 21% survived 12 months or longer.

Our initial experience with palliative PDT involved 44 patients with lung cancer and symptoms related to obstruction and hemoptysis.¹⁰ Thirteen patients required a second treatment course at a mean of 2.3 months for recurrent symptoms. There were no fatalities, and 82% of treatments were performed without complications. Hemoptysis was effectively palliated in 90% of treatment courses. Obstruction was successfully palliated in 59% of treatments. Median survival was 2.3 months. PDT has also been shown to be effective in palliating hemoptysis and dyspnea in patients with endobronchial metastases from malignant neoplasms of nonpulmonary etiology.¹² An example of a patient who was treated for a complete lobar obstruction is demonstrated in [Figures 6-2 through 6-6](#). In general, we have not used PDT for massive hemoptysis for practical reasons; those best suited have subacute but persistent hemoptysis of low volume and have visible endoluminal granular tumor with a bleeding surface area.

In a randomized prospective study, PDT was compared with standard laser techniques for inoperable non-small cell lung cancer.¹³ The bronchoscopic response rate (PDT, 38.5%; laser, 23.5%) and symptomatic improvement at 1 month were equivalent in each group. PDT

FIGURE 6-5 ■ Bronchoscopic picture after photodynamic therapy.

provided significantly longer-lasting relief (50 days vs. 38 days) and improved median survival (265 days vs. 95 days) compared with laser resection. However, this finding may be explained in part by the lower proportion of advanced-stage tumors seen in the PDT group.

FIGURE 6-6 ■ Radiographic picture after photodynamic therapy.

In general, PDT is well tolerated with minimal morbidity. All bright light and direct sunlight exposure must be avoided initially. Patients remain photosensitive for 4 to 8 weeks, after which they can be gradually reexposed to sunlight.^{14,15} Inadvertent direct sunlight exposure has been reported to cause first- and second-degree burns in up to 10% of patients.¹⁶ The restrictions imposed by photosensitivity and their potential impact on quality of life should be considered before treatment. Immediate postprocedure mortality for lung and esophageal PDT (30-day) ranges from 2.6% to 7.1%, but in large part is due to the comorbidities and advanced stage of many of the patients in these series.^{11,13-15}

Barrett Esophagus and Esophageal Cancer

Curative Intent

The management of high-grade dysplasia associated with Barrett esophagus is controversial. In the recent past, most surgeons advocated esophagectomy because of the associated risks of occult malignant disease and lymph node metastases.¹⁷ On the other hand, concerns related to the morbidity and mortality of esophagectomy have led some clinicians to advocate alternative approaches, such as surveillance, endoscopic mucosal resection, or mucosal ablation.¹⁸ In our experience, we have reported good results and a mortality of approximately 1% with a minimally invasive esophageal resection for patients with Barrett esophagus and high-grade dysplasia.^{19,20} Currently available mucosal ablative methods include

endoscopic mucosal resection, PDT, laser ablation, argon plasma coagulation, and radiofrequency ablation.²¹⁻²⁴ All these techniques attempt to resect or eradicate Barrett epithelium with the hope that it will be replaced by squamous epithelium. Unfortunately, in some instances, islands of columnar epithelium may recur under a normal-appearing squamous epithelial layer leading to difficult detection.²⁵ This problem is addressed by other endoscopic techniques, such as initial endoscopic mucosal resection or endoscopic submucosal dissection, whereby the esophageal mucosa is actually resected piecemeal. An in-depth discussion of endoscopic resection techniques is beyond the scope of this chapter, but it should be noted that this approach has become the standard of care in many centers for properly selected patients.

PDT is arguably the most established of these ablative techniques. In a large single-institution study, PDT was combined with the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser to treat 73 patients with high-grade dysplasia and 14 patients with low-grade dysplasia.²⁶ All patients were observed endoscopically for 12 months. Regression to low-grade dysplasia or no dysplasia was observed in 88% of high-grade dysplasia cases and in 93% of low-grade dysplasia cases. Complete eradication of Barrett epithelium occurred in only 9% of patients after PDT alone. In focusing on the PDT-treated area, a 49% eradication rate was reported. The addition of laser ablation to residual areas of Barrett epithelium increased the eradication rate to 87%. In a 5-year prospective randomized multicenter international trial, PDT with Photofrin plus omeprazole was compared with omeprazole only for the treatment of Barrett esophagus with high-grade dysplasia.^{27,28} Complete ablation of high-grade dysplasia was observed significantly more often in the Photofrin group compared with controls (77% vs. 39%). Progression to esophageal cancer was significantly decreased in the Photofrin group (13% vs. 28%). Treatment-related side-effects were more common in the Photofrin group (94% vs. 13%). Strictures developed in 36% of patients, with 98% resolving after dilation. Notably, the benefits on dysplasia resolution and cancer progression persisted at 5-year follow-up. At 5 years, the study demonstrated that the addition of PDT with Photofrin to proton pump inhibitor therapy resulted in a 38% increase in eradication of Barrett esophagus with high-grade dysplasia, a 14% decrease in the incidence of invasive carcinoma, and a longer time to progression to cancer.²⁹

PDT can also be used to treat early-stage esophageal tumors (T1-T2) in patients who are not candidates for surgical resection. In a group of patients that included mostly T1 tumors (12 of 13), regression to Barrett esophagus with low-grade dysplasia or without dysplasia was observed in 77% of patients (10 of 13).²⁶ At our center, PDT with curative intent is reserved for patients with prohibitively high operative risk. All others undergo minimally invasive esophagectomy.¹⁹ We have reviewed our institutional experience, from 1997 to 2005, using PDT for patients with high-grade dysplasia or superficial esophageal cancer.²⁸ A total of 50 patients, who either refused or were unfit for surgery, had PDT with curative intent. The majority of patients (70%) had high-grade dysplasia or small ($\leq$ T1) tumors. At a median follow-up

of 28 months, 32% of patients were alive without recurrence, 30% were alive with recurrent disease, and 38% were deceased from cancer or other causes. The patients with recurrences were retreated with PDT. There was no procedure-related mortality, and the stricture rate was 42%, which were generally easily dilated. Although these results are clearly inferior to esophageal resection, endoscopic ablation appears to be a suitable treatment option for nonsurgical candidates. In another cohort of 28 patients with high-grade dysplasia treated with minimally invasive esophagectomy, 96% remained free of recurrence at 13 months.¹⁹ These results were corroborated by other investigators who have observed excellent long-term survival (100%) after esophagectomy for high-grade dysplasia.²⁹

In the treatment of Barrett esophagus with high-grade dysplasia, PDT is well tolerated with usually transient side effects, such as nausea, regurgitation, constipation, odynophagia, dysphagia, weight loss (average of 6 kg), and noncardiac chest pain.^{30,31} Other complications include stricture, tumor growth below the PDT-induced scarring, and Barrett esophagus and tumor recurrence.³² In our experience, approximately 30% of patients with high-grade dysplasia undergoing PDT will develop an esophageal stricture.²⁸ Stricture is minimized by decreasing the intensity of light therapy compared with doses used for larger tumors.

Another endoscopic treatment modality for patients with Barrett esophagus is radiofrequency (RF) ablation. The components of the system include a sizing balloon (18 to 34 mm), a 3-cm balloon-based bipolar RF electrode, and a dedicated RF generator. The sizing balloon is used to ensure proper contact between the balloon electrode and the esophageal mucosa. The RF mucosal ablation is achieved by using a power of 300 W to deliver 10 to 12 J/cm². The coagulum is then removed from the esophageal surface by irrigation and suction. The maximum ablation depth is 1 mm, which translates to a depth of injury that is superficial to the muscularis mucosa.³³ The depth of injury is highly reproducible and has been confirmed in the human esophagus. In addition to the circumferential balloon electrode, the approval of an RF ablation device that can be attached to the end of a flexible esophagoscope can be used to ablate focal areas of esophageal mucosa. Encouraging results have been published showing complete eradication of Barrett mucosa and intramucosal carcinoma when RF ablation was used in combination with endoscopic mucosal resection.³⁴

With further analysis, it seems that patients with high-grade dysplasia without visible raised or nodular lesions are the optimal candidates for endoscopic management with RFA. The presence of visible lesions requires the addition of a mucosal resection technique to allow for adequate staging and treatment.

Visible lesions containing high-grade dysplasia or intramucosal carcinoma can be treated successfully with RFA, but only as an adjunct to a mucosal resectional technique such as endoscopic mucosal resection.

The Surveillance vs. Radiofrequency Ablation (SURF) trial was a randomized multicenter trial conducted in Europe that randomized patients with a confirmed histologic diagnosis of Barrett esophagus with low-grade dysplasia to treatment with either RFA or standard

endoscopic surveillance (at 6, 12, 24, and 36 months). RFA was demonstrated to significantly reduce the risk of progression to high-grade dysplasia or esophageal adenocarcinoma compared with standard endoscopic surveillance (1.5% vs. 27%) while also reducing the risk of progression to esophageal adenocarcinoma (1.5% vs. 8.8%).

Palliative Intent

Stenting of the esophagus is often the most commonly used modality to palliate dysphagia³⁵; however, PDT offers some advantages in certain clinical situations. In addition to relieving obstruction, PDT can often be used to control or prevent tumor bleeding. It can also prevent the globus sensation associated with stents in the proximal esophagus and the reflux symptoms observed with stents bridging the gastroesophageal junction. PDT is a potential alternative to stenting for endoluminal cancers in both of these locations.

PDT has been compared with laser ablation in a randomized trial. PDT was equivalent to laser ablation for malignant dysphagia and was associated with a lower rate of perforation (PDT, 1%; laser, 7%).³⁶ We reviewed our experience with PDT in 215 patients suffering from obstructing esophageal cancer.³⁷ The most common pathologic process was adenocarcinoma (83%). The distal esophagus was involved in 71% of cases. Dysphagia improved in 85% of patients, and bleeding was successfully controlled in 90%. Stenting was subsequently required in 24% of patients. As expected, median survival was poor at 4.9 months; however, effective palliation lasting 3 to 4 months was provided to many of these unfortunate patients. In another prospective series of 77 patients for whom conventional therapy had failed or who were deemed unfit for surgery, investigators reported a median survival of 6.3 months after PDT.¹⁴ The only significant predictor of mortality was clinical stage. Photosensitivity appears to be an acceptable tradeoff in these patients. In one study using satisfaction questionnaires, patients reported that the ability to swallow food was more important than the limitations of photosensitivity.²⁹ In most cases, the potential benefits of PDT far outweigh the risk of complications.

In patients with obstructing aerodigestive tumors, PDT can result in adverse events. Esophageal strictures (4.8% to 5.2%), perforation (0% to 9.1%), and esophagorespiratory fistulas (0% to 5.2%) are among the most serious PDT-related complications.^{7,14,38-40} Esophageal perforation and fistula are probably best treated by esophageal stenting. Other factors contributing to the mortality rate and risk of esophageal perforation include the generally poor performance status of this particular group of patients with advanced tumors and the fact that some patients with obstructing tumors receive concurrent radiation therapy and chemotherapy.

LASER ABLATION OF ENDOLUMINAL TUMORS

Although several types of lasers including carbon dioxide, argon, potassium titanyl phosphate, and diode are

available throughout medicine, the most commonly used endoscopic laser in thoracic surgery is the Nd:YAG laser. The Nd:YAG laser energy can be delivered through a small-caliber fiberoptic conduit, thus making it ideal for use with the flexible bronchoscope or esophagoscope. Adjustments in power level allow either photocoagulation (low power) or thermal necrosis (high power) of tissue. Depending on the energy level selected, the laser can penetrate tissue depths ranging from millimeters to several centimeters in depth. Airway and esophageal Nd:YAG laser procedures can be performed safely with sedation alone. During the past 25 years, experience with laser photoresection has led to the emergence of clinical safety guidelines and the characterization of lesions ideally suited to laser therapy. Communication among the surgeon, the anesthesiologist, and the rest of the operating team is essential to minimize risks to the patient and staff during laser procedures. The fractional inspired oxygen (FiO₂) should be set to the lowest possible level required to maintain adequate oxygenation, and it should never exceed 40% because of the risk of airway fire. Experienced centers have published a set of simple rules to increase the safety of lasers in the airway (Box 6-1).⁴¹ These rules, often referred to as the “Ten Commandments,” are also applicable to the esophagus. Other investigators have contributed an excellent mnemonic, “The

BOX 6-1 Adaptation of Dumon's 10 Commandments of Pulmonary Laser Photoresection

1. Know the anatomy. The aortic arch, the pulmonary artery, and the esophagus are danger zones.
2. Have a well-prepared laser team that includes an anesthesiologist specialized in conscious sedation and two assistants equipped with emergency response procedures.
3. Any endoluminal growth is amenable to lasering, but purely external compression is a contraindication.
4. Use the rigid bronchoscope with two suction catheters for high-grade obstruction, especially if a malignant neoplasm is involved.
5. Monitor blood gases and cardiac performance. At the least sign of hypoxemia, interrupt treatment long enough to oxygenate the patient, if necessary under closed-circuit conditions.
6. Fire parallel to the wall of the airway. Never aim directly into it.
7. Coagulate at will but avoid using the laser at high-power settings; mechanical resection after laser coagulation is preferable to laser resection alone whenever possible.
8. Control hemorrhage. Even slow bleeding will lead to hypoxemia if it is left unattended.
9. Terminate each procedure with a thorough laser irradiation of the resected area and a tracheobronchial toilet to remove all secretions or debris.
10. Observe and monitor the patient in the recovery room for a reasonable time.

BOX 6-2 “Rule of Fours” for Optimal Outcome from Endobronchial Nd:YAG Lasering

LESION

- Length of lesion $\leq$ 4 cm
- Duration of collapse $<$ 4 weeks

INITIAL SETTINGS

- Power: 40 watts
- Pulse duration: 0.4 second

DISTANCES

- Endotracheal tube to lesion $>$ 4 cm
- Fiber tip to lesion: 4 mm
- Flexible bronchoscope to tip: 4 mm

TECHNIQUE

- FiO₂ $<$ 40%
- Number of pulses between cleaning $<$ 40
- Procedure time $<$ 4 hours
- Total number of treatments $<$ 4
- Life expectancy $>$ 4 weeks
- Laser team: 4 persons

Nd:YAG, Neodymium:yttrium-aluminum-garnet.

Adapted from Lee P, Kupeli E, Mehta AC: *Therapeutic bronchoscopy in lung cancer: laser therapy, electrocautery, brachytherapy, stents, and photodynamic therapy*. *Clin Chest Med* 23:241–256, 2002.

Rule of Fours,” to remember favorable lesion characteristics, power and pulse settings, and techniques to optimize the results of airway lasering (Box 6-2).⁴² Lesions of the central airways less than 4 cm in length, localized to one wall, and protruding through the lumen (e.g., exophytic, pedunculated) without complete obstruction are ideal for laser ablation.⁴²

Airway

Symptomatic relief from cough, dyspnea, hemoptysis, and postobstructive pneumonia and accelerated weaning from mechanical ventilation can be achieved in approximately 80% of patients with malignant airway obstruction who are treated with laser therapy.⁴² In a series of more than 1800 patients treated with Nd:YAG laser, 93% had improvement in symptoms and quality of life.⁴³ Even in patients with advanced tumors for whom radiotherapy and chemotherapy have failed, 64% may experience symptomatic relief after laser ablation.⁴⁴ Nd:YAG lasering is successful in controlling hemoptysis in 60% of patients; however, recurrence should be expected within 30 days of treatment.⁴⁵ At least 50% of patients can be extubated immediately after laser treatment.⁴² There is no difference in response between primary and metastatic airway lesions. Success rate decreases from 90% to 60% in patients with central airway tumors.⁴⁶

The overall complication rate of laser ablation varies between 0% and 2.2%.⁴² Serious complications include perforation of vascular structures and endobronchial fire, which usually involves the endotracheal tube, the flexible bronchoscope sheath, or suction catheters. As stated

before, fires can be avoided by keeping the FiO₂ below 40%, using nonflammable anesthetic agents, and keeping the scope and field as clean as possible. Hemorrhage from the tumor, pneumothorax, and pneumomediastinum are other recognized complications of airway lasering.

Esophagus

Malignant tumors of the esophagus are also amenable to treatment by Nd:YAG laser. Depending on the size of the tumor, several weekly treatments may be necessary to provide significant relief from obstruction. Lasering can also be used to recanalize a tumor in preparation for stenting. The best candidates for laser therapy are patients with small ($<$ 5 cm) exophytic tumors located in the middle esophagus, at the site of a previous esophagogastric anastomosis, or above a stent. The incidence of laser-related esophageal perforation varies between 0% and 6%.^{47,48} Recurrence of dysphagia can be expected within 4 to 6 weeks of treatment. The combination of laser ablation with radiotherapy has prolonged the dysphagia-free interval in patients with malignant obstruction.⁴⁹

BRACHYTHERAPY

Brachytherapy can be defined as the placement of interstitial or intracavitary radioactive sources to facilitate the safe delivery of high radiation doses with relative sparing of normal surrounding tissues. High-dose-rate brachytherapy allows the delivery of high doses of radiation to the airway during a short period with minimal effect to surrounding tissue. Typically, bronchoscopy is performed with sedation and local anesthesia. A blind-ended 6-French afterloading catheter is passed through the working channel of a bronchoscope, and dummy seeds are placed within the catheter to confirm its position by fluoroscopy. The catheter is taped securely, and the patient is transferred to the radiation suite. Radiation seeds (¹⁹²Ir) are then placed in the afterloading catheter. Typically, a few treatments will be required over 2 to 3 weeks, each session requiring only 10 to 15 minutes of radiation exposure. An advantage of brachytherapy over Nd:YAG laser therapy is the greater depth of penetration (0.5 to 2 cm) compared with laser therapy, making it more suitable for tumors with a predominantly extraluminal component. A disadvantage is that symptomatic improvement will be slower to occur than with PDT or Nd:YAG laser therapy. On longer follow-up, bronchitis with stricture (9% to 13%) or hemoptysis (7%) can develop as a result of brachytherapy^{42,50}; these two complications are more commonly encountered with high radiation doses to the central airways. Symptomatic improvement after brachytherapy occurs in 72% to 94% of cases, depending on the symptom.^{42,51} Endobronchial tumor regression may be observed in 54% to 94% of patients.⁴² Complete histologic response has been documented in up to 72% of early-stage lung cancers.⁵² Finally, there are prospective randomized data suggesting that the combination of brachytherapy and external beam radiation leads to further improvement in symptom-free interval and quality of life.⁵³

STENTS

Malignant endoluminal obstruction and extraluminal compression by enlarged lymph nodes or tumor are common indications for stenting of the airway or esophagus. The two major types of stents used in thoracic surgery are expandable metal stents and silicone-based stents.

Expandable Metal Stents

Expandable metal stents are constructed with cobalt alloys (Wallstent, Schneider), stainless steel (Gianturco, Cook), or a nickel-titanium alloy referred to as *nitinol* (Esophacoil [Medtronic] or Ultraflex [Microvasive]). These materials are resistant to corrosion and are biologically inert, even in patients who are allergic to nickel. The wire stents can be woven (Wallstent), knitted (Ultraflex), or bent into a zigzag (Gianturco) or coil (Esophacoil) configuration. The stent design influences its retraction properties (i.e., shortening). Retraction percentage is highest with the coil configuration and lowest with the zigzag configuration. The shape memory characteristics of the materials allow the stent to reexpand to its original tubular shape, even when it is compressed into a delivery system. The available systems can deploy the stent from the proximal end, the center, or the distal end. Proximal delivery is better suited for proximal strictures, and distal delivery is best for strictures of the gastroesophageal junction. Expandable metal stents can also be partially covered with polyurethane or silicone (e.g., Alimaxx-E, Alveolus; Polyflex, Microvasive; Ultraflex). Covered designs help to reduce tumor ingrowth but have a propensity for migration.⁵⁴ The wide range of available diameters and lengths allows expandable metal stents to fit most upper aerodigestive strictures. More recently, endoluminal clips that are easy to deploy have been used successfully to secure the upper border of the stent to the esophageal mucosa to minimize migration.

Silicone-Based Stents

Silicone-based stents are made of silicone rubber (Silastic, Dow Corning), a ubiquitous component of industrial, household, and medical equipment. Celestin esophageal tubes have fallen out of favor because of the need for an open gastrotomy for anchoring and the higher complication rate in comparison with expandable metal stents.⁵⁵

Flanged (Hood, Hood Laboratories, Pembroke, MA) or studded (Dumon, Bryan Corp., Woburn, MA) cylindrical silicone stents are used in the trachea or bronchi. T-, Y-, and T-Y-shaped silicone stents are also available to treat tracheal and proximal tracheobronchial strictures. If a silicone stent has to be shortened to fit the patient's airway, the manufacturer can provide a customized replacement on request. Silicon stents play an important role in problem areas at or near the cricopharynx. In this location, the funnel-like proximal end may sit above the cricopharynx for intervals of up to several weeks to allow a complex injury or fistula to heal. We also have used these with great success in proximal

tracheal strictures in the shape of a T-tube for proximal airway injuries or a T-Y for extension into the distal airway near the carina.

Technique

Expandable Metal Stents

The procedure can be performed with either conscious sedation or general anesthesia. The stricture is identified endoscopically and measured. Esophageal stents are available in a wide range of lengths (60 to 150 mm), but in contrast to airway stents, most have a similar maximal internal diameter (17 to 23 mm). If the opening of the stricture is too small to accept the endoscope, the lumen may require dilation and laser ablation before length can be assessed accurately. Fluoroscopy is then used to mark the location of the stricture on the patient's skin. This is done with two radiopaque markers (e.g., small stylets, paper clips) that are aligned with the tip of the endoscope when the endoscope is positioned at the proximal and distal edges of the stricture. Alternatively, some clinicians prefer to inject the submucosa at the proximal and distal ends of the tumor with a radiopaque liquid (Conray). Once the measurement of the tumor length is completed, the proper stent is selected. In general, we use an 18- to 23-mm-diameter stent that is 1 to 2 cm longer than the stricture to avoid crimping and infolding of the ends. A guidewire is passed through the stricture, and the endoscope is withdrawn. Under fluoroscopic control, the delivery system is inserted over the guidewire through the stricture and aligned with the skin or mucosal markers. The stent is deployed and expands within the lumen. Proper positioning and deployment are confirmed fluoroscopically and endoscopically. A postprocedure chest radiograph (in all cases) and barium esophagogram (in esophageal cases) are obtained. Expandable metal stents are popular because they are easier to insert and do not require expertise in rigid bronchoscopy. Silicone stents are more challenging to place but may be less problematic in the long term for specific applications. We prefer these stents for patients with benign strictures of the proximal airway or esophagus.

Silicone-Based Stents

Unless the patient has a tracheal stoma, rigid bronchoscopy is needed to insert a silicone-based stent. A chest tube and the stent are passed over a rigid scope in sequence. The chest tube serves as a pusher to deliver the stent over the rigid scope. For Y-shaped stents, the right mainstem bronchus limb is invaginated, and the rigid scope is passed through the left mainstem bronchus limb. After it is positioned, the scope is pulled back within the tracheal limb, and biopsy forceps are used to push out the right-sided limb. An alternative technique is to guide the right-sided limb into the right mainstem bronchus with a Fogarty catheter while positioning the proximal portion of the stent endoscopically. A complete technical description of rigid endoscopic stent insertion has already been published.⁵⁶ Table 6-1 compares some of the features of silicone and metal stents.

TABLE 6-1 Characteristics of Silicone and Expandable Metal Stents

Stent Type	Description	Method of Insertion	Pros	Cons
Silicone Based				
Internal	Made of Silastic rubber Straight or Y shaped Studded (Dumon) Flanged (Hood) Silicone mesh with outer polyester coating (Polyflex)	Rigid endoscopy	Resistance to lateral compression Prevents ingrowth Easier to remove	Eliminates mucociliary clearance (airway) Propensity for mucus plugging (airway) Propensity for dislodgment (airway and esophagus)
External	T or T-Y shaped	Rigid bronchoscopy or per tracheal stoma	Maintains tracheal stoma Tracheal port allows suction Prolonged relief of dyspnea in nonoperative candidates Custom-fitted	Cosmesis Regular maintenance (irrigation, suction)
Expandable Metal				
Internal, partially or fully covered or noncovered	Nickel-titanium (Ultraflex) Cobalt-steel (Wallstent) Steel (Gianturco) Fully covered (Alimaxx-E, Aero)	Flexible endoscopy	Easy to insert Adapt to irregularly shaped stricture Potentially removable (fully covered)	Weaker expansile force Granulation Allow ingrowth of tumor (noncovered) Nonremovable (noncovered)

Indications

The recommended definitive treatment of focal benign airway strictures is surgical resection. Stenting is indicated for strictured or malacic airways that are not amenable to resection or in nonsurgical candidates in whom dilation or laser resection has failed. Stenting can also be used as a bridge to surgery in patients needing time for their general condition to improve or for the scar to mature. It should be clear that stenting of benign strictures as definitive treatment is suboptimal therapy, as 40% of patients will need reintervention.⁵⁷

Malignant airway strictures, especially those caused by extrinsic tumor compression, can be managed with stenting. In the esophagus, stents are indicated for obstruction or esophagorespiratory fistula associated with malignant disease.

Benign Airway Strictures

Stenting of benign airway strictures should be regarded as second-line therapy, reserved for situations in which surgical resection is not possible. In comparison with the shorter survival expected with malignant strictures, patients with benign strictures live longer and require further intervention over time. For this reason, silicone stents are recommended. Previous experience with silicone stents for benign strictures in nonoperative candidates has been relatively good.^{58,59} Of 112 patients with T stents, only 5 (4.5%) required removal for obstructive problems, and 85% were managed successfully for periods of 3 months to more than 5 years.⁵⁹ In another case series, 94% of patients with benign strictures had successful palliation of obstruction.⁵⁷ Only 3 of 54 silicone stents (5.6%) needed removal or replacement for migration or compression, and the mortality rate was 12.5% at 4 years

of follow-up. Other studies involving smaller numbers of patients (6 to 22) reported symptomatic and spirometric improvement after stenting.⁶⁰⁻⁶² In one report, it was acknowledged that granulation tissue is a common finding (up to 80% of patients), which may lead to removal in 20% of cases.⁶²

Our experience supports the use of silicone-based stents over expandable metal stents for benign strictures. In a cohort of 36 patients, reintervention was necessary in 61% of patients at a mean of 6 months. Nd:YAG laser was required to ablate granulation in a significantly higher number of patients with metal stents compared with silicone stents. One in five expandable metal stents had to be removed for complications. Extirpation of uncovered metal stents required thoracotomy in 33% of cases. Despite their relative ease of insertion, uncovered expandable metal stents should probably be avoided in nonsurgical candidates with benign airway strictures. A newer silicone-based stent (Polyflex) may be a reasonable temporizing measure. It may be useful in benign strictures associated with inflammation, in which case luminal patency can be maintained while airway remodeling and fibrosis take place. Although the stent is made of silicone, the outside polyester mesh coating can render removal difficult.

Malignant Airway Strictures

Because most patients with malignant airway obstruction usually have a limited survival from the time of stenting, the emphasis should be placed on preserving quality of life more than on the particular type of stent used. Surgeons familiar with silicone stents have achieved relief of dyspnea in 87% to 94% of patients.^{57,63} Complications, including migration and occlusion, occurred in 12.5% to 23.1% of stents placed. Mortality was 68.7%, at a mean

interval of 7.6 months.⁶³ Polyurethane-covered expandable metal stents can also provide significant improvement in dyspnea and Karnofsky score; however, up to 55.6% of patients experience complications, including stent migration in 22.2%.⁶⁴ Although covered stents prevent tumor ingrowth, they have a propensity for dislodgment.

In malignant airway obstruction, stenting is part of a multidisciplinary approach to palliation. In the majority of the studies discussed before, patients received chemotherapy or radiation therapy in addition to stenting. The importance of adjuvant therapy has been highlighted in a prospective trial.⁶⁵ In 22 patients with tracheobronchial strictures treated by stenting, 50% eventually had the stent removed after appropriate radiation therapy and chemotherapy regimens.

We recently reviewed 53 cases in which expandable stents were used to treat tracheobronchial obstruction.⁶⁶ Concurrent interventions included balloon dilation (29%), Nd:YAG laser (29%), PDT (23%), rigid bronchoscopy with débridement (15%), and brachytherapy (2%). Bronchoscopic patency was achieved in 92% of patients. Radiographic improvement was noted in 46% of patients with lung collapse. Reintervention was required in 19 patients (36%) for obstruction by mucous plugging or granulation tissue. The median post-stenting survival was relatively short, at 41 days.

Benign Esophageal Strictures

In benign esophageal strictures, routine use of stents cannot be recommended in light of a 41% rate of stent-induced restenosis and almost uniform (91%) recurrence of dysphagia.^{67,68} In some selected cases when an anastomotic stricture is recalcitrant to repeated endoscopic dilations, insertion of an esophageal stent that is potentially removable (e.g., Alimaxx-E, Polyflex) may be an acceptable option. It has even been suggested that this approach may be as effective clinically and less costly than repeated endoscopic dilations.⁶⁹ We have reported our initial experience with removable esophageal stents (Polyflex) to manage at least 25 patients with benign esophageal strictures, including those associated with an anastomotic leak after esophagectomy.⁷⁰ Although dysphagia was significantly improved after stenting, distal migration was a significant problem that occurred in more than two thirds of the patients. Stenting failed to seal anastomotic leaks and malignant tracheoesophageal fistula in 38%. It is hoped that future changes in removable esophageal stent design will address the significant problem of migration. The recent introduction of endoscopically placed clips has allowed us to fix the upper border of the stent to the esophageal wall with good short-term success in preventing migration.

Malignant Esophageal Strictures

Depending on the referral pattern, up to 80% of malignant esophageal tumors will be inoperable at the time of diagnosis. Endoscopic palliation with laser or stents assumes a preponderant role in providing relief from dysphagia to many of these patients. During the past

decade, advances in expandable stent technology have led to smaller, more flexible delivery systems that are easier to manipulate than their silicone counterpart. These attributes often allow successful stent deployment with minimal or no endoscopic dilation, thereby minimizing the risk of perforation.

Both silicone-based and mesh wire stents are susceptible to tumor overgrowth above and below the stent, leading to recurrence of esophageal obstruction. In addition, ingrowth of tumor through noncovered mesh wire interstices can occur. In the absence of an esophagorespiratory fistula, the decision to use a covered stent is influenced by the potential for recurrent obstruction by tumor ingrowth and the likelihood of stent migration. When tumor overgrowth or ingrowth occurs, therapeutic modalities including PDT, laser, and further stenting (i.e., placement of a stent within a stent) may be of additional palliative benefit.¹⁶

Few studies have compared silicone and expandable metal stents in a prospective randomized fashion.^{55,71} In comparable groups of patients, technical success (95% to 100%), improvement in dysphagia (91% to 100%), and the need for reintervention were similar regardless of stent type. However, the use of silicone stents was associated with a higher rate of complications (43% to 47% for silicone stents vs. 0% to 16% for metal stents) and a longer hospital stay (silicone, 6 to 12 days; metal, 4 to 5 days). Although 30-day mortality was not significantly different (silicone, 29%; metal, 14%), death resulting from stent insertion occurred only in the silicone stent group.⁵⁵ Despite a higher purchase price, expandable metal stents were found to be more cost-effective because of shorter hospitalization and lower complication rates.⁴¹

At the University of Pittsburgh, a review of 100 stented patients demonstrated relief of dysphagia in 85%, with a low probability of perforation (0.8%) and no short-term fatalities.¹⁶ Reasons for initial stent failure were inability to resume oral diet, intractable reflux and pain, bulky tumors resulting in inadequate stent expansion, and inadequate stent position. Sixteen stents were placed in patients undergoing neoadjuvant therapy before esophagectomy. Supplemental enteral or intravenous nutrition was not necessary in 88% ($n = 14$) of those patients. At the time of esophagectomy, dissection of the periesophageal planes was more difficult, but no postoperative complications could be attributed directly to preoperative stenting. Patients receiving chemotherapy or radiation therapy at the time of stenting may be prone to perforation or fistulization and local abscess formation.^{16,72,73} Although this has not been evaluated in controlled trials, alternatives to stenting should be considered in this subgroup of patients. Fully covered esophageal stents may be a better choice in this situation. These stents can be used for temporary relief of dysphagia and can provide the necessary time window for chemotherapy or radiation therapy to take effect and then proceed with stent removal when a tumor response has been obtained making the stent unnecessary. In other large series of patients undergoing stenting (≥ 100 patients), placement was successful, and improvement of dysphagia was observed in 90% to 100%.⁷⁴⁻⁷⁸ Patients were stented with a mortality of 0% to 2.5% and a complication rate of 20%

to 41%. These findings lend additional support to the use of stents as a relatively safe and effective method of palliation for obstructing esophageal cancer.

COMPARISON OF PALLIATIVE ENDOSCOPIC THERAPIES

We have described a number of different approaches to palliate obstruction or bleeding from endoluminal tumors. Because most of these patients have a shortened life expectancy, the goals of therapy should be to improve symptoms and quality of life and to minimize morbidity and hospital stay. No randomized trials are available to compare these modalities. The perception among physicians that palliative treatment modalities are complementary rather than alternative has caused difficulties in patient accrual for randomized trials.⁷⁹ Typically, a center will favor one approach over another. It is our opinion that the thoracic surgeon should be familiar with all these modalities, as many clinical scenarios will require the combination of various treatment modalities. An example

is given of our approach to palliation of obstructing lung cancer (Fig. 6-7). The relative merits of each treatment modality are summarized in Table 6-2.

EVOLVING ENDOSCOPIC TREATMENT MODALITIES FOR BENIGN ESOPHAGEAL DISEASES

Achalasia

Historically, the management of achalasia has included a collection of medical, endoscopic, and surgical treatments aimed at symptom palliation and targeted at the incomplete relaxation of the lower esophageal sphincter. Medical treatment with nitrate and calcium antagonists assist in smooth muscle relaxation, often improving the symptom of chest pain, but they are limited by their poor efficacy and side effects.⁸⁰⁻⁸² Until recently, the only available endoscopic treatments included Botox injections and pneumatic dilation. Although initially successful in 90% of patients, Botox injections at the gastroesophageal

junction last typically less than 6 to 9 months and are therefore reserved for older patients or nonoperative candidates.⁸³ Pneumatic dilation was originally shown to offer short-term success rates similar to those seen with a laparoscopic Heller myotomy with Dor fundoplication.⁸⁴ A recent multicenter randomized study demonstrated equivalent clinical success between the two approaches at 2-year follow-up,⁸⁵ but on further long-term evaluation pneumatic dilation was noted to have a failure rate of 50% to 60%. To date, laparoscopic Heller myotomy with Dor fundoplication remains the treatment of choice in young or otherwise healthy patients.⁸⁴

In 2008, the first human cases of per-oral endoscopic myotomy were published. Since then, per-oral endoscopic myotomy has been gaining traction as a developing endoscopic treatment for achalasia that combines the surgical element of a controlled myotomy with the low impact of an endoscopic approach.

Key steps of the procedure include: (1) marking of the distal end of the dissection 2 cm distal from the gastroesophageal junction on the short curvature; (2) creation of the submucosal lift using a saline injection; (3) opening of the submucosal channel using sharp dissection with a cautery knife; (4) injection of lifting solution through the balloon allows correct delineation of the submucosal plane; (5) sharp dissection of the circular muscle fibers; (6) intraoperative retroflexed view confirming 2 cm extension of myotomy onto stomach wall; and (7) multiple clip closure of the mucosal defect. This technique requires advanced endoscopic skills and a learning curve of at least 20 cases.

Per-oral endoscopic myotomy is highly successful with intermediate-term clinical results demonstrating an average dysphagia relief of 98%. The most common long-term complication is gastroesophageal reflux (GER) with an estimated incidence of 35%, similar to the incidence of GER after laparoscopic Heller myotomy with fundoplication. GER symptoms are present in 0% to 44% of patients, with a reported anti-acid use of 0% to 50% after per-oral endoscopic myotomy. Endoscopic evidence of erosive esophagitis is present in 0% to 43% of patients, and positive pH studies is present in 0% to 38% of patients. Although these numbers reflect a high incidence of postoperative GER, they are in fact similar to the 21% to 42% of abnormal pH studies after laparoscopic Heller and partial fundoplication.^{86,87}

Patients are often discharged home on the morning of the first postoperative day and return to work an average of 3 days after the intervention. Although per-oral endoscopic myotomy represents a paradigm shift in the treatment of achalasia, additional long-term data are needed to further define its role in the treatment algorithm of achalasia and possible role in other esophageal pathologies, such as diffuse esophageal spasm, nonrelaxing hypertensive lower esophageal sphincter (LES), and nutcracker esophagus. We have been impressed that in experienced hands, there has been a low incidence of serious complications such as clinical perforations or abscesses with good initial relief of dysphagia. However, we stress the importance of a careful approach to this procedure using animal models to gain an understanding of the procedure and then a prolonged series of cases with an experienced proctor present. In our opinion, this procedure should only be considered by surgeons with significant experience in laparoscopic, thoracoscopic, and open esophageal surgical experience with the treatment of achalasia.

Zenker Diverticulum

The pharyngoesophageal diverticulum was first described by Ludlow⁸⁸ in 1764 but was methodically characterized by Zenker in 1867.⁸⁹ Killian elegantly described the anatomic relationship of the diverticulum and Killian triangle, where it arises.⁹⁰ For many years this finding has been referred to as a condition that occurs for unknown reasons as the upper sphincter seemingly for no reason, fails to open with the initiation of the pressures of swallowing to propel the food bolus beyond the cricopharyngeus, leading to an outpouching through the Killian triangle. In our clinical experience and that of a few other centers, there is an increasing awareness of the correlation of a Zenker diverticulum and the globus sensation that precedes this, with the coexistent finding of longstanding GER disease (GERD) and initial failure of the LES. It is our opinion that this abnormally tight and unrelaxing upper esophageal sphincter is not an aberrant freak of nature but is more likely a triggered neurogenic response of the upper sphincter to maintain a tighter than normal tone to contain the refluxate coming up from an incompetent lower esophageal sphincter from coming up

through a lax upper sphincter. In fact, on careful examination, we have seen small to moderate hiatal hernias and preceding GERD symptoms in the majority of patients with a Zenker diverticulum. Regardless of the etiology, surgical treatment is indicated to treat symptoms of dysphagia, regurgitation, and aspiration pneumonia. Surgical options include open cricopharyngeal myotomy alone, diverticulectomy and myotomy, and diverticulopexy and myotomy. In 1993, Collard first published a small case series of patients treated with the transoral stapling approach.⁹¹ Each technique is briefly reviewed; the transoral technique is described in detail.

Open Approaches to Zenker Diverticulum

Cricopharyngeal myotomy is an attractive option in the surgical treatment of Zenker diverticula, because the risks of complications are low and the underlying cause of the problem is addressed. Belsey⁹² noted that small diverticula disappeared when a myotomy alone was performed. However, when the pouch is large, myotomy alone does not yield satisfactory results.⁹³ In our opinion, myotomy alone should probably be reserved for the treatment of small (≤ 2 cm), symptomatic diverticula.

The combination of a myotomy with a diverticulectomy became popular in the 1960s, and several groups reported lower morbidity and lower recurrence rates when the two procedures were done simultaneously.⁹³⁻⁹⁶ Lerut⁹⁵ reported a significant decrease in morbidity from 21% to 11% when a myotomy was performed at the time of diverticulum resection.

Suspension of the diverticulum to the retropharyngeal fascia or to the anterior spinal ligament combined with a myotomy is another acceptable surgical option that we prefer for the management of symptomatic Zenker diverticulum. This approach avoids the potential morbidity of a leak at the site of diverticulum resection. Konowitz reported no morbidity in patients undergoing diverticulopexy and myotomy versus 20% morbidity for those undergoing diverticulectomy and myotomy.⁹⁷ Additional literature to support the routine use of this technique over diverticulectomy and myotomy is lacking.^{93,98,99} With very large diverticula, we prefer to resect these at the time of myotomy because they can be difficult to pexy if they are larger than 6 to 8 cm.

Transoral Endoscopic Stapling

Transoral stapling of the common septum between the diverticulum and the esophagus gained popularity after the first series by Collard, published in 1993.⁹¹ The procedure can result in shorter anesthetic time, decreased hospital stay, and reduced complication rates compared with open procedures. In a recent review of series of transoral stapling published between 1993 and 2002, 541 of 576 (94%) attempted staplings were completed successfully, and 96% of the patients had a satisfactory outcome. The incidence of major complications was 3%, and 2.6% of the patients had a perforation or leak.¹⁰⁰

In our own experience, we have performed more than 100 transoral staplings and have found this to be an ideal approach if the following are present⁹⁰: (1) minimum

diverticulum size of 2 cm, (2) edentulous patient, (3) ability to fully extend the neck without restriction and absence of cervical spine abnormalities, (4) low Mallampati classification (I-II), (5) absence of a receding lower jaw, (6) classified as an easy intubation with traditional anesthetic criteria, and (7) desire by the patient to avoid open surgery.

Patient Positioning. The first step to a successful endoscopic stapling is patient selection. Ideal patient characteristics are ability to fully extend the neck without restriction, low Mallampati classification (I-II), edentulous mouth, and adequate diverticulum size (>2 cm).¹⁰¹ The procedure is performed under general anesthesia with a single-lumen endotracheal tube. The patient is supine with a small pillow placed for back support and to allow extension of the neck. The surgeon is behind the patient's head.

Endoscopy. All patients should undergo flexible endoscopy, and the esophagus should be carefully inspected for any associated pathologic process (e.g., hiatal hernia, Barrett esophagus). Care must be taken to find the true esophageal lumen. We have found that leaving a guide-wire in place temporarily can confirm the true esophageal lumen. After a thorough flexible endoscopy, the Weerda rigid endoscope (Karl Storz, Tuttlingen, Germany) is inserted into the patient's mouth (Fig. 6-8). A 5-mm straight or 30-degree thoracoscope connected to a video camera is used to improve visualization through the rigid endoscope or just lateral to it. The blades of the Weerda scope are opened gently to demonstrate both the true esophageal lumen and the lumen of the diverticulum. If needed, the diverticulum is cleaned of any residual contents with the help of suction and saline irrigation. The septum between the diverticulum and true esophageal lumen should be well demonstrated.

FIGURE 6-8 ■ The Weerda rigid endoscope. One blade is placed in the esophagus and the other in the diverticulum. (From Morse CR, Fernando HC, Ferson PF, et al: Preliminary experience by a thoracic service with endoscopic transoral stapling of cervical [Zenker's] diverticulum. *J Gastrointest Surg* 11:1091-1094, 2007. Used with permission, Springer Verlag.)

FIGURE 6-9 ■ Traction stitch placed in the septum with use of 2-0 Ethibond on an Endo Stitch device (U.S. Surgical Corp., Norwalk, CT). This prevents the septum from being “squeezed” out of the stapler jaws. (From Morse CR, Fernando HC, Ferson PF, et al: Preliminary experience by a thoracic service with endoscopic transoral stapling of cervical [Zenker’s] diverticulum. *J Gastrointest Surg* 11:1091–1094, 2007. Used with permission, Springer Verlag.)

FIGURE 6-10 ■ The modified Endo GIA 30 stapler (U.S. Surgical Corp., Norwalk, CT). The anvil is modified by shortening the tip to allow the staple to go to the base of the septum. The *white arrow* indicates an unmodified anvil. The *black arrow* indicates an anvil modified by removal of the tapered end. (From Morse CR, Fernando HC, Ferson PF, et al: Preliminary experience by a thoracic service with endoscopic transoral stapling of cervical [Zenker’s] diverticulum. *J Gastrointest Surg* 11:1091–1094, 2007. Used with permission, Springer Verlag.)

Stapling. To facilitate the insertion of the stapling device, a traction suture is placed on the septum, separating the true lumen of the esophagus and the diverticulum, by use of the Endo Stitch device (Covidien, Dublin, Ireland; Fig. 6-9). An Endo GIA 30-mm with Tri-staple technology (Covidien) is used for stapling. We prefer the smaller stapler height so that the staple line can reach the base of the septum and still allow visualization (Fig. 6-10). The stapler is inserted through the rigid endoscope, and the jaws are placed across the septum, in the midline (Fig. 6-11). The suture provides countertraction on the septum during placement and firing of the endostapler.

Results. The two largest series on transoral stapling of Zenker diverticula come from Italy.^{102,103} Peracchia and colleagues¹⁰³ reported experience with 95 attempted transoral staplings of Zenker diverticula. Ninety-two patients (97%) had successful stapling. Two patients had limited neck extension, and one patient had a mucosal tear during the procedure. All three patients had an open procedure without complications. The author reported that the three unsuccessful attempts occurred in the early years of the series. Satisfactory outcome was achieved in 94% of the patients, and 5% had recurrence or persistence of the diverticula. Narne and colleagues¹⁰² described 102 patients, of whom 98 (96%) had successful stapling. A satisfactory outcome was achieved in 96% of patients, with a 4% recurrence rate and no major morbidity.

We presented our results with transoral stapling in 24 patients.¹⁰⁴ Of the 28 patients enrolled, the procedure was completed in 24 patients (85%). Four patients had conversion to an open procedure because of unfavorable anatomy (two patients), perforation of the diverticula (one patient), and a diverticulum smaller than 2 cm (one patient). There were no other significant complications, and the length of stay was 2.2 days. Time to oral intake was 1.38 days, and dysphagia scores improved remarkably after the procedure (2.78 to 1.1).

In experienced hands, transoral stapling is a safe, rapid, and effective way to treat Zenker diverticula. Surgeons contemplating the use of this approach should be familiar with rigid esophagoscopy and open surgical management of Zenker diverticula.

Gastroesophageal Reflux

Gastroesophageal reflux disease (GERD) is defined as the presence of symptoms, such as heartburn or regurgitation, or the presence of esophageal mucosal damage secondary to acid reflux. Up to 44% of the population will experience heartburn at least once a month, and 17.8% will at least once per week,¹⁰⁵ making GERD the third

most common gastrointestinal disorder in the United States. It is responsible for 96,000 hospitalizations per year, at a cost of almost \$10 billion.¹⁰⁶ GERD significantly impairs quality of life and may have a worse impact on patients than angina pectoris and congestive heart failure. After initial medical therapy, only 10% to 25% of patients will remain symptom free 6 months after stopping medications; the rest require long-term medical therapy.¹⁰⁷ Up to 20% of GERD patients receiving proton pump inhibitors (PPIs) will experience breakthrough symptoms.¹⁰⁸ The daily dependence on medications, the high associated costs, and the suboptimal symptom control have spurred interest in minimally invasive endoscopic approaches to GERD.

For historical completeness, endoscopic procedures for GERD can be classified into three major groups: RF therapy to the lower esophageal sphincter (Stretta, Curon Medical, Fremont, CA), injection of biopolymers at the gastroesophageal junction (Enteryx, Boston Scientific, Natick, MA), and endoscopic plication of the gastroesophageal junction. These treatment modalities are mentioned for completeness, as they are no longer commercially available. Endoscopic plicators (e.g., Esophyxx, EndoCinch) are currently approved for use in the United States.

Radiofrequency Therapy to the Lower Esophageal Sphincter

Curon Medical, the manufacturer of the Stretta system, stopped making the device after filing for bankruptcy in November 2006. The devices delivered low-power RF energy to the gastroesophageal junction. The procedure involved the delivery of RF energy to the esophageal tissue from 1 cm above the gastroesophageal junction to a level immediately below the squamous-columnar junction. The proposed mechanisms of action for the Stretta procedure include mechanical alteration of the gastroesophageal junction and neural modulation of the lower esophageal sphincter, resulting in decreased relaxation and acid exposure.^{109,110}

The short-term results (6 to 12 months) of a prospective study of 118 patients showed significant improvement in DeMeester score, lower esophageal sphincter pressure, heartburn score, GERD health-related quality of life (GERD-HRQL) score, and Short Form 36 (SF-36) questionnaire score.¹¹¹ At baseline, 88% of patients required daily PPIs compared with 30% at 12 months. An ad hoc analysis of the results concluded that symptomatic improvement after the Stretta procedure correlated with decreased lower esophageal sphincter acid exposure, linking symptomatic improvement with proximal and distal esophageal acid control.¹¹²

Corley¹¹³ conducted a blinded, randomized, controlled trial in 64 patients with GERD. At 6 months, treated patients showed a significantly improved heartburn score, GERD-HRQL score, and general quality of life. There was no difference between the groups in daily medication use, median 24-hour pH score, and lower esophageal sphincter pressure or esophageal mucosal erosions. This trial showed that the Stretta procedure was effective in improving symptoms and quality of life but failed to

improve acid exposure or healing of mucosal lesions. The authors could not explain the findings. In the largest published study, Wolfsen¹¹⁴ evaluated GERD symptoms, patient satisfaction, and medication use in 558 patients treated in 33 centers. Mean follow-up was 8 months, ranging from 2 to 33 months. Satisfaction of patients improved from 23.2% to 86.5%, symptom control improved from 50% to 90%, and 77% of patients reported absent or mild GERD after the Stretta procedure compared with 26.3% at baseline. Subset analysis showed that improvement persisted beyond 1 year after the procedure, and most patients did not require antacid medication.

In summary, the Stretta procedure appears to be effective in controlling GERD symptoms in a select group of patients. However, questions about the precise mechanism of action and the long-term effects are likely to remain unanswered and have led our group to use other approaches.

Injection of Biopolymers at the Gastroesophageal Junction

Enteryx is a biocompatible polymer in the form of a nonviscous liquid that solidifies rapidly when it is injected into tissue, becoming an inert spongy mass. The procedure was usually performed under fluoroscopic guidance, and most treatment sessions placed 1-mm blebs circumferentially around the gastroesophageal junction. Enteryx injections can be repeated if symptoms are not fully controlled; however, it is not reversible.¹¹⁵ The proposed mechanism of action of Enteryx injection to the lower esophageal sphincter is the prevention of lower esophageal sphincter unfolding or relaxation in response to gastric distention in an effort to prevent reflux and improve lower esophageal sphincter tone.¹¹⁶

A prospective, multicenter international trial of Enteryx implantation for GERD was conducted, and 12- and 24-month follow-up data are available.^{117,118} Results were reported for 85 patients for 12 months and for 144 patients for 24 months. Patients entered the trial if their symptoms were well controlled and symptom scores were normalized with PPIs and returned to abnormal levels after withdrawal of PPIs. At 12 months, 84% of the patients had a reduction in use of PPIs of more than 50%, and 73% of the patients stopped using PPIs completely. This effect was maintained at 24 months; 72% of patients had a reduction in use of PPIs of more than 50%, and 67% had complete cessation of PPIs. GERD-HRQL score improved in 78% of the patients at 12 months and in 80% at 24 months. Median heartburn score improved in 71% at 12 months and in 80% at 24 months. Regurgitation score improved in 77% at 12 months and 88% at 24 months. The median score of the physical component of the Short Form-36 questionnaire improved by 12%, but the mental component did not change significantly. Esophageal manometry was not significantly changed at 12 months. Esophageal acid exposure declined significantly at 12 months. Median supine, upright, and total acid exposure times were decreased by 42%, 28%, and 31%, respectively. Thirty-seven percent of patients had acid exposure normalized 12 months after the

procedure. At 12 months, esophagitis was unchanged in 59 patients (55%), decreased in 14 patients (13%), and increased in 34 patients (32%). Of the 34 patients with an increase in esophagitis, 19 had increased by one level and 14 by two levels. One patient had an increase in esophagitis from 0 to III. Adverse effects in the trial were relatively minor, with retrosternal chest pain being the most frequent. One patient had a paraesophageal fluid collection, which was treated conservatively. Outside the trial, serious adverse events were reported. One patient died of gastrointestinal bleeding from an aorto-esophageal fistula and was found on autopsy to have Enteryx material embedded in the aorta. Another patient developed severe flank pain and was noted to have embolization of Enteryx to his aorta and renal arteries.¹¹⁹ The U.S. Food and Drug Administration ordered a recall of the product in 2005. Although the international trial demonstrated good symptomatic relief in patients with GERD controlled with PPIs, 30% worsening in esophagitis and reports of fatalities preclude us from recommending this treatment option.

Endoscopic Plication of the Gastroesophageal Junction

Esophyx. The transoral incisionless fundoplication procedure attempts to restore the angle of His and improve the antireflux mechanism by creating an omega-shaped valve, 3 to 5 cm in length and 200 to 300 degrees in circumference, through the use of transorally inserted full-thickness endoscopic fasteners. The Esophyx device is essentially an overtube with a channel for the esophagoscope and a flexible section that retroflexes and compresses the tissue at the angle of His.¹⁰⁴ Clinical details are limited. A canine model did not show any adverse effects, and the fasteners were effective in creating a stable serosa-to-serosa fusion at 1 year.¹²⁰ Animals with a circumferential valve demonstrated a significant and lasting increase in the lower esophageal sphincter pressure, decreased esophageal acid exposure, and decreased DeMeester score. Cadiere and colleagues¹²¹ published a series of 17 patients treated with the Esophyx device. One year after surgery, GERD-HRQL score improved by 67%, 82% of patients discontinued PPIs, and more than 80% were either satisfied or very satisfied with the procedure. Endoscopy at 1 year revealed that 81% of the valves maintained their tightness, median circumference, and length. Grade A and B esophagitis was observed in 13 patients, and hiatal hernias remained reduced in 8 of 13 patients. Long-term results have not been substantiated; this combined with technical difficulty of performing the procedure and the inability to yield a consistent valve have led our group and most others to abandon this approach.

EndoCinch. The EndoCinch (Bard Medical, Covington, GA) requires an overtube and two endoscopes, one for the suturing and the other for suction and visualization. The procedure entails plication of a fold of mucosa just below the squamous-columnar junction. Three sutures are placed below the gastroesophageal junction in a circumferential, linear, or helical pattern.¹²²

Sham-controlled trials of the EndoCinch have had remarkably different results. Rothstein and colleagues,¹²³ in a single-blinded trial, compared 78 patients undergoing the EndoCinch procedure with 81 patients undergoing a sham procedure. At 3 months, more than 50% of patients undergoing the EndoCinch procedure had an improvement in the GERD-HRQL score, as opposed to only 18% in the sham group. In addition, patients treated with EndoCinch had a significant improvement in pH acid exposure and a higher rate of discontinuation of PPI therapy (50% vs. 24%). There were no significant complications in the treated patients.

In contrast, Montgomery and coworkers¹²⁴ randomized 46 patients to the EndoCinch procedure or sham endoscopy. At 12 months, the investigators could not demonstrate differences between groups regarding GERD-HRQL score, PPI use, acid exposure, or esophageal manometric findings. At 12 months, 33% of the EndoCinch sutures were not visible, leading the investigators to conclude that the detachment of the sutures led to failure of the procedure. Both sham and EndoCinch subjects had significant improvements in GERD symptoms and PPI use after 12 months. The procedure was performed without major complications. In another sham-controlled trial, Schwartz and colleagues¹²⁵ randomized 60 patients to EndoCinch therapy, sham procedure, or observation alone. Heartburn symptoms and the use of PPIs were significantly decreased after EndoCinch compared with sham or control. Quality of life was also significantly improved in treated patients compared with sham patients. Esophageal acid exposure did not significantly differ between the treatment and the sham groups, although both groups experienced a reduction in overall acid exposure after 3 months.

Results of a North American multicenter trial were published in 2005. Eighty-five patients were enrolled and observed for 24 months.¹²⁶ Patients had a significant improvement in heartburn symptoms, and 77% reported no or minimal heartburn and no or minimal regurgitation in 2 years. Forty percent of patients reported complete cessation of use of PPIs at 24 months, and the annualized per patient medication costs decreased from \$1564 at baseline to \$183 at 2 years. Esophageal acid exposure was also significantly decreased at 6 months. One patient experienced severe dysphagia requiring removal of the fundoplication sutures 10 days after the procedure.

NDO Plicator. The NDO Plicator (NDO Surgical, Mansfield, MA) was designed to create a full-thickness plication of the gastroesophageal junction by delivery of a suture-based implant. This is accomplished by direct visualization of the gastroesophageal junction in a retroflexed fashion with a pediatric endoscope inserted through a dedicated channel of the plicator device. The plication is done 1.0 to 1.5 cm below the Z line, and either one or two plications are performed. Unfortunately, because of insufficient demand for the device, the company filed for bankruptcy in 2008.

In the North American open-label multicenter trial, 64 patients were treated with one plication with the NDO Plicator.¹²⁷ At 12 months of follow-up, the

GERD-HRQL score improved from 19 to 7 ($P < 0.0001$). The proportion of patients receiving daily PPI therapy decreased from 93% to 32% at 12 months. At 6 months, there was significant improvement in acid exposure at the distal esophagus, with both the number of episodes and the total acid exposure time showing significant improvement. In a randomized, sham-controlled trial of 159 patients, 56% of plicator patients versus 18.5% of sham patients had an improvement of more than 50% in the GERD-HRQL score at 3 months.¹²³ Discontinuation of PPI therapy occurred in 50% of the treated patients and 24% of the sham patients at 3 months. Most adverse effects included mild chest and epigastric pain. One patient underwent laparoscopy for persistent epigastric pain and was found to have adhesions between the stomach and the diaphragm. In another study of 33 patients observed for 5 years, there was a significant improvement of the GERD-HRQL score, and 33% had completely discontinued PPI therapy.¹²⁸ Adverse effects included sore throat (45%), abdominal pain (41%), chest pain (24%), and transient dysphagia not requiring dilations (21%).

In summary, endoscopic fundoplication is a procedure in evolution that has demonstrated short-term effectiveness in controlling symptoms of GERD. In general, patients with dysphagia, severe esophagitis, Barrett metaplasia, previous esophageal or gastric surgery, or a type I hiatal hernia larger than 2 cm were excluded from these trials. Most of the trials were also industry sponsored. Overall, it appears that patients with a very small hiatal hernia and a good response to PPIs may be the best candidates for endoluminal therapy. At this time, this treatment modality should probably be reserved for non-surgical candidates or those who refuse surgery. The role of endoluminal fundoplication in the management of GERD will be further delineated once more complete long-term follow-up data become available.

With technological advancement, these minimally invasive techniques may improve and become even more attractive to patients. It is important for thoracic surgeons to remain aware of further developments and to continue to critically evaluate new therapeutic modalities as they are introduced into clinical practice.

First-line therapy for GERD includes medical management with acid suppressing proton pump inhibitors, often providing incomplete control of reflux symptoms in nearly half of patients. As the pathologic cause of GERD lies in the incompetence of the lower esophageal sphincter, it has been demonstrated that sphincter augmentation may improve barrier function without altering the hiatal and gastric anatomy or interfering with swallowing, belching, or vomiting. A newly introduced sphincter augmentation therapy includes the LINX Reflux Management System by Torax Medical, Inc.

The LINX device is a small band of titanium beads with magnetic cores placed around the LES, the magnetic attraction allows for resistance to gastric distention while allowing for opening during the presence of esophageal swallowing forces thus preventing reflux and improving the natural barrier of the LES.

The magnetic attraction between the beads is intended to help the LES resist opening to gastric pressures,

preventing reflux from the stomach into the esophagus (see Fig. 6-1). LINX is designed so that swallowing forces temporarily break the magnetic bond, allowing food and liquid to pass normally into the stomach (see Fig. 6-2). Magnetic attraction of the device is designed to close the LES immediately after swallowing, restoring the body's natural barrier to reflux. A prospective assessment of 100 GERD patients who underwent sphincter augmentation with the LINX device demonstrated decreased esophageal acid exposure, symptomatic improvement, and reduction in use of PPI therapy. Outcomes at 3 and 5 years were reported. Normalization of esophageal acid exposure or a 50% or greater reduction in exposure at 1 year was achieved in 64% of patients. Improvement in quality of life related to gastroesophageal reflux disease and a reduction in the use of proton-pump inhibitors at 1 year occurred in 93% of patients. The most frequent adverse event was dysphagia (68% of patients postoperatively, 11% at 1 year, and in 4% at 3 years). Serious adverse events occurred in six patients, and six patients requested to have the device removed.¹²⁹

The median time needed to implant the device laparoscopically was 36 minutes (range, 7 to 125 minutes). All patients were discharged within 1 day after surgery, with an unrestricted diet. As the field of thoracic surgery continues to change and evolve, it is important for thoracic surgeons to continue to expand their armamentarium of available therapies.

COMPLICATIONS OF THORACIC TRAUMA

Acute Lung Injury and Respiratory Distress Syndrome
Pneumonia
Pleural Space Problems
Bronchopleural Fistula
Great Vessel Fistula

The earliest recorded reference to thoracic trauma is found in *The Edwin Smith Surgical Papyrus*, written around 3000 BC.¹ In this report of 58 cases, three were related to the chest: a penetrating injury to the cervical esophagus, a stab wound to the sternum, and blunt trauma resulting in rib fractures. Homer reported on many thoracic injuries during the Trojan War in his *Iliad*, perhaps the most famous of which occurred when King Agamemnon slayed Odius during the Battle of Troy with a well-placed spear through his chest.² At the start of the common era, there are descriptions of fatal thoracic injuries suffered by the ancient Olympians in their often more violent version of the familiar games, as well as those suffered by the gladiators and depicted by Galen.^{3,4} Many of these injuries were the focus of art in the ancient world (Fig. 7-1).⁵ More recent was the well-known assassination attempt of President Ronald Reagan by John Hinckley on March 30, 1981, whose bullet struck the president in his left chest, causing a nonfatal hemothorax (Fig. 7-2).^{6,7} In the most recent conflicts in Afghanistan and the Middle East, Operation Enduring Freedom and

Operation Iraqi Freedom, respectively, thoracic trauma was observed in 8.6% of all casualties, carrying an almost 10% associated mortality rate. Penetrating trauma was the most common mechanism of injury (61.5%). Changes in warfare have borne out with explosive devices now representing the most common cause of thoracic injury.⁸

Through the eras of Hippocrates and Galen, open packing and local treatment with common ingredients (red meat, honey, lint) was the mainstay of treatment, until the thirteenth century when wound débridement and closure was advocated. However, wound closure became a topic of great debate somewhat clarified by Paré in 1514. He advocated immediate closure of wounds without blood or a small amount in the chest, enlargement of small wounds if better drainage of blood was required, and delay of wound closure until blood drainage had ceased (usually 2-4 days).⁹ During the next century, various cannulas were developed to irrigate infected wounds and empyemas; these cannulas eventually evolved into the closed drainage systems during World War II.

FIGURE 7-1 ■ *The Dying Gaul*, from the first or second century BC, the Capitoline Museum of Rome. Note the penetrating trauma to the right hemithorax. (From Churchill ED: Chest wounds in ancient sculpture. *J Hist Med Allied Sci* 26:304–305, 1971.)

FIGURE 7-2 ■ Chest radiograph following the assassination attempt of President Ronald Reagan on March 30, 1981. Note the presence of a left-sided chest tube and a bullet fragment near the left border of the heart. (From Rockoff SD, Aaron BL: The shooting of President Reagan: a radiologic chronology of his medical care. *Radiographics* 15:407–418, 1995.)

Also during this conflict, thoracotomy became commonplace not only as the most effective means in draining retained blood and infected debris, but also to remove the peel that formed over the lung from the hemothorax. As thoracic surgical principles developed, so too came advances in endotracheal intubation, mechanical ventilators, and thoracic pain control that became pivotal in the management of most thoracic injuries over the next several decades.

As a result, mortality from chest wounds had progressively decreased from a wartime high of 80% to 90% as reported by Billings during the American Civil War¹⁰ to 8.3% in a 10-year review of Operation Enduring Freedom and Operation Iraqi Freedom⁸ to 4% to 7% in

recent civilian experience. Nevertheless, thoracic trauma accounts for 25% of all trauma deaths, representing approximately 160,000 deaths annually.¹¹ More than 70% of thoracic injuries result from blunt trauma, most of which are due to automobile accidents. One in four cases with cardiothoracic trauma regardless of etiology requires hospital admission.

Age of the patient plays an important role in the severity of injuries. In the pediatric patient where the immature chest wall is elastic and flexible, fractures are rare, but intrathoracic injuries are more significant. In older patients, the fragile bony thorax is highly susceptible to even low-impact forces, and it offers poor protection for the underlying viscera. Mortality is high, even with minor injuries.

Penetrating injuries are uncommon on either extreme of age groups, but they remain one of the most common causes of death from trauma up to the age of 40 years. Low-velocity handguns, seen primarily in the civilian population, transmit little damage to surrounding tissues. Conversely, much more damage and energy is conducted along the path of high-velocity missiles, usually associated with the military, but now often seen in community violence.

PRIMARY SURVEY

The standard resuscitation of the trauma patient has been outlined by the American College of Surgeons in the *Advanced Trauma Life Support* (ATLS) guidelines.¹² Upon the patient's arrival in the trauma bay, it is crucial to rapidly perform a primary survey with attention to the airway, breathing, and circulation (the ABCs) so that potentially life-threatening injuries can be recognized immediately before they become lethal. Following this algorithm, first the airway must be controlled; second, breathing is assessed and immediately assisted with mechanical ventilation if necessary. Next, circulation must be supported through the rapid establishment of reliable, large-bore venous access and the initiation of fluid resuscitation. Finally, the patient's neurologic disabilities are assessed, and the entire body is exposed to identify any significant deformities or penetrating injuries that might have been overlooked. The goal of the primary survey is to identify immediate, life-threatening injuries that could account for ventilatory or hemodynamic compromise, which if left uncorrected could cause death.¹³

Injuries to the thoracic cavity or its contents comprise the majority of this group, and generally speaking they require urgent intervention as a life-saving measure. These life-threatening injuries and preferred treatment measures are listed in [Table 7-1](#). These problems should always be kept in mind during the resuscitation of every trauma patient. The mechanism of injury should also influence the index of suspicion for these injuries, as some are more likely to be sequelae of blunt trauma (aortic rupture, diaphragmatic hernia, cardiac tamponade), penetrating trauma (cardiac tamponade, massive intrathoracic hemorrhage), or common to both (pneumothorax).

TABLE 7-1 Potentially Acutely Lethal Injuries of the Chest and Their Management

Injury	Management
Tension pneumothorax	Tube thoracostomy
Massive intrathoracic hemorrhage	Tube thoracostomy, operative repair
Cardiac tamponade	Pericardiocentesis, operative repair
Deceleration aortic injury	Operative repair
Massive flail chest with pulmonary contusion	Intubation, pain control, fluid restriction
Upper/lower airway obstruction	Intubation, airway, bronchoscopy
Tracheobronchial rupture	Bronchoscopy, operative repair
Diaphragmatic rupture with visceral herniation	Operative repair
Esophageal perforation	Operative repair

DIAGNOSTIC TESTS

Approximately one third of all deaths from thoracic trauma occur immediately or shortly thereafter when transported to a treatment facility. Diagnostic and emergency management modalities are essential to evaluate these injuries fully and to direct care toward the proper therapeutic interventions.¹⁴

Chest Radiography

The chest radiograph remains paramount in every trauma victim and should be the central focus from which potential life-threatening thoracic problems are suspected. Chest radiographs can be obtained rapidly upon arrival to the trauma bay with the patient still on the transportation backboard. A systematic review of the film should reveal suspected and unsuspected injuries, and the presence of any foreign bodies. Fractures of the bony thorax, including the ribs, clavicles, spine, and scapulae, should be excluded. Fractures of the thoracic cage indicate significant energy transfer to the patient; those of the upper ribs are associated with trauma to the great vessels, and those of the clavicle are associated with pulmonary or cardiac contusions. The lung fields should be examined for pneumothorax, hemothorax, or pulmonary contusion. Along the mediastinum, widening, pneumomediastinum, or shifting are highly suggestive of aortic transection, tracheobronchial or esophageal injuries, or tension pneumothorax or hemothorax. The soft tissues may reveal subtle subcutaneous air or foreign bodies. Finally, the width of the cardiac silhouette may raise the suggestion of tamponade.

Computed tomography (CT) is not essential for every patient with chest trauma and should not be performed in the severely hemodynamically unstable patient or in the presence of obvious life-threatening injuries; however, it can be done with rapidity, and may reveal injuries not seen clearly on plain radiographs: aortic disruption, pneumothorax, pneumomediastinum, hemothorax, or pulmonary contusions. It may be useful to screen all patients with blunt trauma and to evaluate unusual or

abnormal findings on an initial chest radiograph (e.g., diaphragmatic injuries).

CT of the chest has been shown to be more sensitive at detecting thoracic injuries such as pulmonary contusions, hemothorax, and pneumothorax.^{15,16} Up to 75% of trauma patients with a normal physical examination and chest radiograph will have an occult injury diagnosed on chest CT, and 5% of these patients will need intervention for their injuries.^{17,18} Even when evidence of thoracic trauma is seen on a physical examination and plain radiography, the addition of chest CT leads to altered management and therapeutic decisions in up to one third of all patients with thoracic injuries.^{16,17} In addition, chest CT can be used to exclude diagnoses made by the less sensitive chest radiograph, which can happen in up to 15% of patients.¹⁷ More recently, the routine use of CT in the evaluation of thoracic trauma has been scrutinized because of the cost and time associated with performing and interpreting this test. The NEXUS Chest decision instrument is one model that has arisen to potentially mitigate these unnecessary expenses. In using seven clinical criteria to predict thoracic injury seen on chest imaging with major clinical significance and as indicators to proceed with CT, the NEXUS Chest instrument yielded a sensitivity of 99.7% and a negative predictive value of 99.9%.¹⁹

Ultrasonography

Ultrasonography has become fairly routine in the early evaluation of the abdomen and pericardium.²⁰ Termed the *focused assessment for the sonographic evaluation of the trauma patient* (FAST) examination, four standard viewing ports are used to quickly assess for abnormal fluid collection: right upper quadrant, left upper quadrant, pelvis and subxiphoid. In addition, the E-FAST, or extended-FAST, that uses an extension of the right and left upper quadrant views to include the right and left hemithoraces—right and left longitudinal thoracic views, respectively—can aid in the diagnosis of hemothorax or pneumothorax (Fig. 7-3).^{21,22} Recent meta-analyses have demonstrated that ultrasound is more sensitive in detecting traumatic pneumothoraces than conventional supine chest radiography is; however, supine anteroposterior radiographs remain superior in regard to specificity.²³ Although not as precise as an ultrasound performed by a board-certified radiologist or cardiologist, this examination is able to detect fluid collections that might influence the need for urgent operative intervention. Of the four views, the subxiphoid view is the most accurate in the hands of surgeons in detecting abnormalities in the trauma setting.²⁰ It has the advantages of being safe, expeditious, repeatable, and effective even in the hands of surgeons from different specialties,²⁴ and it can be useful to identify injuries to the heart and fluid in the pericardium.

Echocardiography

There has been a major shift in the diagnosis of aortic and great vessel injuries in recent times.²⁵ In the 1990s and earlier, these injuries were diagnosed almost exclusively with aortic angiography and/or transesophageal

FIGURE 7-3 ■ The extended focused assessment for the sonographic evaluation of the trauma patient, or E-FAST, examination using four standard viewing ports (numbered): right upper quadrant, left upper quadrant, pelvis, subxiphoid, and the extended views of the left and right hemithoraces (*asterisks*). (From Körner M, Krötz MM, Degenhart C, et al: Current role of emergency US in patients with major trauma. *Radiographics* 28:225–242, 2008.)

echocardiography (TEE). Over the past decade there has been a major shift toward CT angiography as the most prevalent diagnostic modality in this patient population, with only a small percentage of patients undergoing conventional angiography or TEE. In two large trauma center reviews, CT angiography was found to be 90% to 95% sensitive and to have a 99% to 100% negative predictive value, making it useful as a screening modality.^{26,27} Meta-analyses of smaller case series from the literature over the past two decades appear to support these conclusions with sensitivity and negative predictive values approaching 100%.²⁶

Cited reasons for the shift in diagnostic modalities include technical improvements in the quality of CT angiograms with the addition of multi-row detector CT techniques to the standard helical CT, the relative ease of performing the test, reliable interpretations of rapidly obtained results, cheaper cost to perform the test, ability to perform real-time three-dimensional (3D) reconstructions, and the ubiquitous nature of CT machines in emergency departments across the nation. This examination can be performed at the same time as the common whole-body CT scan that many trauma patients undergo as part of their routine workup. Furthermore, the level of detail achieved with CT aortography far exceeds that from conventional aortography, allowing the radiologist and the surgeon to identify even the most subtle of aortic injuries that may have been missed on conventional aortography. Cardiac gating, an emerging technique, is used to limit motion artifact and has rendered questionable arterial lesions on routine CT amenable to better characterization. Large case series have identified CT aortography as

FIGURE 7-4 ■ Conventional angiogram demonstrating aortic transection injury just distal to the left subclavian artery.

an appropriate medium for screening, diagnosing, and planning operative repair of aortic injuries.²⁷

In addition, unlike CT angiograms, results and interpretation from TEE are extremely user-dependent, and the expertise requires an understanding of the anatomic structures and of the sensitivity levels of the machine. The new role for TEE may be reserved for its ability to detect and follow small intimal tears not seen on angiography and intraoperative imaging before and after a repair.

Angiography

Conventional angiography was once the gold standard in the diagnosis of aortic transection or injuries to the great vessels (Fig. 7-4).²⁸ In aortic transection, the classic aortographic image displays a pseudoaneurysm near the site of the isthmus. Partial or complete interruption of the aortic contour may be seen when the aortic wall has retracted, or if debris of the wall prolapses into the lumen. Occasionally, a ductus diverticulum (i.e., Kommerell diverticulum), a normal finding at the site of the ligamentum arteriosum, may be mistaken for aortic injury.²⁹

The role of conventional arteriography is unclear at the present time, as many centers currently use highly detailed, 3D aortic reconstructions alone for diagnosis and operative planning (Fig. 7-5). Others will obtain a conventional aortogram if the results of the CT angiogram are equivocal or if the study was technically inadequate. Still others will routinely get conventional arteriograms to confirm the presence of an aortic injury before surgical intervention.³⁰ When performed, a retrograde femoral arteriogram is the preferred study. Generally agreed upon indications for aortography in these patients either by conventional methods or CT angiography are listed in Box 7-1.

In fact, the use of conventional aortography for further evaluation of patients whose CT angiography has been read as indeterminate is unlikely to diagnose any aortic

FIGURE 7-5 ■ Aortic injury with saccular aneurysm (arrows) following chest trauma as seen by CT angiogram (A) and three-dimensional reconstruction (B). (From Steenburg SD, Ravenel JG, Ikonomidis JS, et al: Acute traumatic aortic injury: imaging evaluation and management. *Radiology* 248:748–762, 2008.)

or other great vessel injuries, and thus may no longer be part of the evaluation of these patients.³¹ Thus, some have argued that the role of conventional angiography is limited to centers without adequate multidetector CT scanners with software for 3D reconstruction and an available radiologist for interpretation, for cases in which artifact from air or metallic objects preclude adequate imaging, or when angiography is used to direct therapy (e.g., embolization of smaller arteries).¹⁴

The presence of a mediastinal hematoma is often the first manifestation of an aortic injury seen on CT angiography (CTA).³² It is important, however, to note the exact location of this hematoma, as hematoma outside of the aortic walls with preservation of the fat plane around the aorta does not represent an aortic injury, but rather usually damage to surrounding periaortic mediastinal vasculature. A hematoma extending from a point adjacent to the aortic wall can be suggestive of a true aortic injury, and careful examination of the remainder of the thoracic CTA is important. Rarely will one see active extravasation

BOX 7-1

Indications for Angiographic Studies for Potential Thoracic Injuries

- High-speed deceleration injuries
- Chest radiography findings:
 - Widened mediastinum
 - Loss of aortic knob shadow
 - Tracheal or esophageal deviation to the right
 - Widening of paraspinal stripe or apical capping
 - Downward displacement of left mainstem bronchus
 - Obliteration of the aortopulmonary window
 - Fractured first rib, sternum, or scapula
 - Multiple rib fractures or flail chest
 - Massive hemothorax
- Upper extremity hypertension
- Unexplained hypotension
- Pulse deficits or asymmetry
- Systolic murmur

of contrast into the mediastinum or thorax, as this type of injury is almost always uniformly fatal.

There are several radiographic signs on CTA that are diagnostic of traumatic aortic injury and should lead to immediate repair without further diagnostic evaluation, especially in patients in unstable condition. These signs include intraluminal thrombi, clear evidence of mural dissection or an intimal flap, and changes to the diameter or contour of the aorta itself. Delay of definitive repair in these patients can lead to increased mortality among this patient population.

EMERGENCY DEPARTMENT THORACOTOMY

The indications for emergency department (ED) thoracotomy have been widely debated.³³ ED thoracotomy clearly plays a role in penetrating thoracic trauma, particularly in the setting of trauma patients with cardiac tamponade from penetrating chest injuries.³⁴ The role of ED thoracotomy for patients with blunt traumatic injuries is heavily debated and appears to be limited. The Western Trauma Association recently published the results of a prospective study involving 18 trauma centers and concluded that resuscitative ED thoracotomy may be considered futile when prehospital cardiopulmonary resuscitation (CPR) for blunt trauma exceeds 10 minutes with no response.³⁵

Thoracotomy allows relief of cardiac tamponade, the ability to perform open cardiac massage, and control of ongoing intrathoracic hemorrhage. In addition, by applying a crossclamp to the thoracic aorta, one can limit intra-abdominal bleeding and improve cerebral and coronary perfusion in the setting of exsanguinating hemorrhage. Patients with penetrating cardiac stab wounds are the most likely population to survive resuscitation with ED thoracotomy; the same is true for other penetrating cardiac injuries. The likelihood of patient survival depends on patient down time, the patient's age and

BOX 7-2 Indications and Contraindications for Emergency Room Thoracotomy

ACCEPTED INDICATIONS

- Unresponsive hypotension (SBP < 60 mm Hg)
- Rapid exsanguination from indwelling chest tube (<1500 ml)
- Traumatic arrest with previously witnessed cardiac activity (pre- or in-hospital) following penetrating thoracic injuries
- Persistent hypotension (SBP < 60 mm Hg) with diagnosed cardiac tamponade, air embolism

RELATIVE INDICATIONS

- Traumatic arrest with previous witnessed cardiac activity (pre- or in-hospital) following blunt trauma
- Traumatic arrest without previously witnessed cardiac activity (pre- or in-hospital) following penetrating chest injuries
- Prehospital cardiopulmonary resuscitation less than 10 minutes in intubated patient, 5 minutes in non-intubated patient

CONTRAINDICATIONS

- Blunt thoracic injuries with no previously witnessed cardiac activity
- Multiple blunt trauma
- Severe head injury

SBP, Systolic blood pressure.

comorbidities, and signs of life on arrival in the ED. General guidelines have been recommended for ED thoracotomies by the American College of Surgeons' Committee on Trauma in the setting of thoracic trauma (Box 7-2).³⁶

Although these general guidelines have been debated, most agree that the best results occur in patients with penetrating cardiac trauma and in whom there is a good likelihood for preservation of cerebral activity. Even with an experienced team and established protocols, results are still poor. The length of time of prehospital CPR has become one of the determinants whether to perform ED thoracotomy. In one report, there were no survivors from ED thoracotomy when prehospital CPR had been in progress in an intubated patient for more than 10 minutes, or more than 5 minutes in a nonintubated patient.³⁷ Another relatively poor marker of outcome is refractory metabolic acidosis monitored during the initial resuscitation efforts, with pH of less than 6.8 or severe base deficits restraining the use of ED thoracotomy. However, signs of life upon presentation to a trauma center nearly quadruple the probability of survival.³⁸

The surgical approach is a left fourth interspace anterolateral thoracotomy. This can be performed with the patient prone or preferably with a few folded blankets placed under the patient's left side to elevate it and to allow the incision to be opened more posteriorly if necessary. The incision can also be carried across the sternum into the right chest if necessary to improve exposure or to evaluate the right side for injury. The pectoralis muscle is divided with a large scalpel, and the intercostal muscles are divided widely using curved Mayo scissors. The

sternum is transected with an oscillating saw, Lebsche knife, Gigli saw and even (if nothing else is available) a good pair of trauma shears. The mammary vessels are divided as they are crossed, and they are ligated once the patient's condition is more stable. The pericardium is opened widely in a cranial, caudal direction, staying anterior to avoid the phrenic nerve. A large pericardiotomy allows easier evacuation of clot, visualization of the heart, and ability to perform more efficient open heart massage. Cross-clamping the descending aorta requires opening the overlying parietal pleura, taking down the inferior pulmonary ligament or retracting the inferior lobe in a superior fashion, and then freeing the aorta from the esophagus bluntly via digital dissection. Care should be taken not to avulse any intercostal vessels. At this point a vascular aortic cross-clamp can be placed across the aorta. Aortic cross-clamp time should be kept to the minimal amount of time (less than 30 minutes) required to resuscitate the patient to avoid the sequelae of spinal cord ischemia and lactic acidosis caused by distal hypoperfusion. When the patient's condition is sufficiently stable, he should be taken immediately to the operating room to definitively manage any injuries and to provide a sterile chest washout with antibiotic irrigation and formal closure of the thoracotomy with wide chest tube drainage.

Even with these extraordinary ED efforts on the part of the trauma team, the results from ED thoracotomy are dismal, with overall survival rates of 1.8% to 27.5%.³³ Although the survival rates of patients who undergo ED thoracotomy vary substantially among case series in the literature, mechanism of injury is the most important factor affecting mortality as patients suffering penetrating injuries are more likely to benefit from this procedure, with mean survival rates of 13% (range, 2.7%–38.9%) compared with a mean of 1% (range, 0%–12%) of patients with blunt injuries. Even among those who survive their injuries after ED thoracotomy, up to half of these patients will have some neurologic deficit, although some authors have reported more than 90% of patients regaining neurological function in their series.³⁸

BLUNT TRAUMA

As mentioned previously, blunt trauma to the chest in the United States is far more common than penetrating injury. A 2002 report by the National Safety Council reported that of all blunt trauma deaths, 25% were due to thoracic trauma. The high-speed deceleration and crush injuries involved in automobile accidents have become increasingly prevalent since the 1950s, and they account for the majority of blunt thoracic trauma. Falls, sports mishaps, assaults, and blast injuries follow. The damage from a powerful blast can be particularly severe as the blast pressure wave imparts a large amount of kinetic energy to a small area. Blast kinetic energy especially affects gas-containing organs, such as the lung, resulting in pulmonary hemorrhage, hypoxia, and shock. In addition, because of the mechanisms that provide the amount of energy needed to produce significant blunt thoracic trauma, many of these patients will have

associated head, abdominal, or extremity injuries along with those of the thorax that are presented here.³⁹ Nevertheless, even among this multiply injured population, the thoracic injuries are responsible for the majority of mortality among these patients.⁴⁰

Chest Wall

Optimal mechanical properties of the chest wall are important determinants for effective functioning of the entire respiratory system. Blunt trauma to the chest wall can disrupt respiratory mechanics and perturb intrathoracic pressure gradients, leading to poor pulmonary toilet and significant morbidity. Chest wall trauma alone occurs in only 16% of cases,⁴¹ and it is often a marker of more ominous visceral injury inside the thoracic cage or below the diaphragm. Since the chest wall, composed of the ribs, sternum, clavicles, and scapulae, provides a protective bony skeleton around the vital organs of the chest, the effect of fracturing each of these bones will be considered.

Rib Fractures

Fracture of the ribs is the most common blunt thoracic injury, occurring in an estimated 300,000 people in the United States during the year 2000, or 39% of patients admitted to major trauma centers.^{42,43} It is important to realize that rib fractures represent an important indicator of trauma severity. The greater the number of ribs fractured, the higher the patient's morbidity and mortality, even from nonpulmonary causes, especially if six or more ribs are broken.⁴³⁻⁴⁵ The number of ribs fractured has been significantly correlated with the presence of hemothorax or pneumothorax, with 81% of patients having either condition if two or more ribs were fractured.⁴⁶ Fractures of the fourth through the ninth ribs are associated with injuries to the lung, bronchus, pleura, and heart, whereas fractures below the ninth rib are indicative of spleen, hepatic, or renal injuries.

The main symptoms include pain, exquisite point tenderness, and possibly crepitus. As the initial examination, an upright chest radiograph should be obtained as a routine part of the trauma series if possible; otherwise, a supine chest radiograph will suffice. In the event that special documentation of a crime, such as child abuse, is needed, rib detail films are performed. Chest radiography alone fails to diagnose rib fractures in more than half of trauma patients with fractures; thus, the addition of CT to the trauma evaluation improves the sensitivity of the diagnosis of rib fractures.⁴⁷ Careless dismissal of a simple rib fracture and underestimating its pathophysiologic potential, especially in older patients, is a common management pitfall. After adjusting for severity of injury, comorbidity, and the presence of multiple rib fractures, older patients (≥ 65 years old) with simple rib fractures still were five times more likely to die compared with patients younger than 65 years.⁴⁸ First rib fracture has particular significance because of the great force required for it to occur and the likelihood that intrathoracic visceral injury has also taken place. The two most common sites of first rib fracture are at the subclavian sulcus and

in the neck of the first rib posteriorly. Subclavian artery and/or aortic arch angiography (conventional or CTA) is indicated if the first rib fracture is displaced posteriorly, the subclavian groove is fractured anteriorly, there is widened mediastinum on chest radiography, or there is an upper-extremity pulse deficit, a concomitant brachial plexus injury, or an expanding hematoma.⁴⁹ In the pediatric population, a chest radiograph can have predictive value in assessing for associated intrathoracic vascular trauma in children with first rib fractures. A normal mediastinum on CXR in the setting of a first rib fracture carried a 100% negative predictive value in a study done at a level 1 pediatric trauma center.⁵⁰

Although binders, cumbersome rib belts, and taping were advocated in the past, the modern approach to treatment emphasizes relief of pain, prevention of atelectasis, and optimization of pulmonary toilet. The importance of adequate analgesia to proper pulmonary toilet is evident by studies showing decreased mortality among patients with rib fractures who received epidural anesthesia.⁴⁵ A prospective case series at a level 1 trauma center found that patients with isolated, simple rib fractures suffered an average over 50 days of disability and lost work and usual activity because of pain.⁴⁴ Interventions favored for short-term pain relief include epidural analgesia, intercostal rib blocks, intrapleural instillation of anesthesia, and intravenously giving opiates and oral nonsteroidal anti-inflammatory drugs.^{42,51-53} More recently, continuous intercostal nerve blockade has been explored as an analgesic adjunct at multiple institutions. Patients with three or more unilateral rib fractures, managed with continuous intercostal nerve blockade through an extrathoracic, paravertebral approach, demonstrated significant improvement in numeric pain scale scores and sustained maximal inspiration lung volumes.⁵⁴ Chronic pain control is invariably required usually with oral narcotics, nonsteroidal anti-inflammatory drugs, and transdermal patches. Patients must be reminded to practice adequate pulmonary toilet after discharge by using an incentive spirometer, deep breathing, coughing, and ambulation. Patients should be counseled that their pain will likely continue for weeks and that sustained need for oral analgesics during this time is not uncommon. In addition to chronic pain, other long-term sequelae include chest wall deformities, persistent dyspnea, and neurologic deficits. A relatively uncommon but potential long-term complication of severe blunt chest wall trauma is a thoracic lung hernia. These entities should be repaired, because they pose a constant threat of incarceration, pneumothorax, or strangulation.⁵⁵

Flail Chest

During the primary survey of a patient who has suffered blunt trauma, careful observation for the presence of a flail chest is imperative because of the associated pathophysiologic derangements that accompany this finding.⁵⁶ This injury usually results from the fracture of four or more ribs at two sites either unilaterally or bilaterally (multiple contiguous rib fractures with multiple fractures of each rib), promoting enough instability that the thoracic cage exhibits paradoxical motion locally as evidenced

by thoracic wall collapse with inspiration. This instability impairs respiratory mechanics resulting in hypoventilation, poor pulmonary drainage, and atelectasis. Patients with flail chest are distinct from those with multiple rib fractures since they are at a higher risk of respiratory compromise and often require early intubation.⁵⁷ Endotracheal intubation is required in more than two thirds of patients with flail chest, and it is indicated for a respiratory rate greater than 40 breaths/minute, or a PO_2 of less than 60 mm Hg despite 60% face-mask oxygen. Relative indications for intubation include shallow respirations, depressed consciousness, pre-existing chronic lung disease, or the presence of associated injuries. In fact, in the presence of multiple injuries, intubation of the patient with a flail chest is almost unavoidable, and early controlled intervention is often preferred to obviate sudden respiratory decompensation and its subsequent morbidity.⁵⁷

A flail chest invariably occurs because of high kinetic energy absorption by the thoracic cage; therefore, it is an important marker for significant intrathoracic injury in patients with blunt trauma. Flail chest is highly associated with pulmonary contusion, which occurs in approximately 45% of patients.⁵⁸ Pneumothorax and hemothorax are common acute sequelae, while acute respiratory distress syndrome occurs in as many as one third of patients, resulting in mortality rates as high as 33%.⁵⁸

Conservative therapy with emphasis on pain relief with thoracic epidural analgesia is the mainstay of therapy in most centers. In a minority of cases, however, patients require chest wall stabilization (Fig. 7-6).^{59,60} These commonly are intubated patients with no possibility of being weaned from the ventilator because of a large unstable flail segment of chest wall. However, recent meta-analyses suggest that chest wall stabilization of flail segments may have significant effects on both morbidity and mortality. Patients who underwent operative management for flail chest were noted to have significantly decreased duration of mechanical ventilation, length of ICU stay, risk for pneumonia, need for tracheostomy, and mortality.^{61,62} A recent prospective randomized trial corroborated a significantly decreased length of ICU stay in patients undergoing chest wall stabilization for flail chest.⁶³

Sternal Fractures

Current estimates suggest traumatic sternal fractures occur in 3-8% of blunt trauma.⁶⁴ Isolated fractures of the sternum are seen with increasing frequency in motor vehicle crashes, particularly since the passing of the mandatory seatbelt legislation because of the rapid deceleration that occurs from this mechanism of injury, especially in vehicles with absent or malfunctioning airbags.⁶⁵ Point tenderness, edema, and obvious deformity are occasionally detected on physical examination, but lateral chest radiography is diagnostic in the majority of patients.

Mortality from isolated sternal fractures remains low (3.5%), and surgical repair is uncommon (<2%).⁶⁶ Some have suggested that patients with isolated sternal fractures, a normal echocardiogram, and no elevation of cardiac enzymes in the early hours of injury will have a benign course. They advocate discharging these patients

FIGURE 7-6 ■ Stabilization of flail segments with wire, Judet staple, intermedullary wire brace and periosteal plates. (From Trunkey DD: Chest wall injuries. In Blaisdel FW, Trunkey DD, editors: *Cervicothoracic trauma*, ed 2, New York, 1994, Thieme Medical Publishers.)

home within 24 hours of arrival in the ED.⁶⁷ Others support selective repair for those with severe deformities or associated chest wall fractures, because this procedure can be performed with low mortality and morbidity with good outcomes.⁶⁸ Surgical management options include metal plates with or without autologous bone grafts.^{69,70} Although an isolated sternal fracture carries a favorable prognosis, other life-threatening concomitant injuries occur in up to one third of patients necessitating careful evaluation and clinical vigilance.

Clavicular Fractures

Management of traumatic clavicular fractures often depends on location. As the clavicles are thin and exposed, the middle third of the clavicle is the most frequently

fractured region of the clavicle, occurring in three fourths of patients with clavicular fractures.⁷¹ The remaining one fourth of clavicular fractures is found in the acromial region and is classified according to the location and integrity of the surrounding ligaments. Type I fractures are found distal to the coracoclavicular ligaments, and the acromioclavicular joint remains intact with minimal displacement of the fracture segments. Type IIa fractures are found medial to the conoid ligament, whereas IIb fractures are found within the coracoclavicular ligaments and involve disruption of the conoid ligament. Type III fractures are again observed distal to the coracoclavicular ligaments, extending into the acromioclavicular joint. Type IV fractures are reserved for the pediatric population and are evidenced by disruption of the epiphyseal plate.

In a type V fracture, a small fragment of clavicle remains attached to the coracoclavicular ligaments with separation from the remaining clavicle.⁷² Fractures of the medial one third of the clavicle are rare. Right and left clavicles tend to be fractured with equal frequency. Clinical examination reveals tenderness, deformity, crepitus, and less commonly upper extremity neurovascular injury. Routine chest radiographs are often sufficient for diagnosis.

Conservative treatment is the preferred practice for medial and middle clavicular fractures, using closed reduction and figure-of-eight slings. This results in normal healing in 95% of patients. Operative intervention is typically reserved for displaced fractures, comminution, or neurologic deficits associated with the fracture. Surgical techniques include placement of steel reconstruction plates and cannulated bone screws. A recent meta-analysis of prospective studies comparing operative (plating or elastic intramedullary nailing) versus nonoperative (sling or bandage fixation) management demonstrated a significantly reduced rate of non-union, malunion, and neurologic complications when surgical intervention is used.⁷³ Late sequelae of clavicular fractures include painful non-unions, altered shoulder mechanics, neurogenic thoracic outlet syndrome, vascular abnormalities, and brachial plexus injuries. Contributing factors to non-union include severe initial trauma, open fracture, marked initial displacement and shortening, soft tissue interposition, primary open reduction and internal fixation, refracture, multiple trauma, and inadequate initial mobilization.⁷⁴

Scapular Fractures

Since the scapula is thick and well protected, scapula fractures are relatively rare and occur usually only after high-kinetic-energy impacts. In fact, many patients with scapular fractures will have other serious injuries to other anatomic sites because of the large transfer of energy needed to produce this type of injury.⁷⁵ Still, they should always be in the differential diagnosis in any patient who complains of shoulder pain or violent muscular contractions about the shoulder after blunt trauma. Most fractures occur in the neck and body, with glenoid, acromion, and coracoid process injuries being less frequent. As is the case with other thoracic cage trauma caused by severe

blunt trauma, associated pulmonary contusions and rib fractures are common. Diagnosis is often difficult on physical examination, occasionally identified by localized tenderness, swelling, and hematoma formation over the fracture site. Scapular fractures are often overlooked on supine chest radiographs, and the three-view trauma series of the shoulder is often necessary to reveal the fracture. Chest CT scans are not recommended.

Immobilization in a sling with pain relief and early range-of-motion exercises is usually all that is needed for recovery of good glenohumeral function. Open surgical reduction is rare. Brachial plexus injuries sustained are often chronic, leading to long-term disability including loss of shoulder mobility. In these patients, a severely debilitated and insensate extremity may occasionally require amputation.

Traumatic Asphyxia

Traumatic asphyxia, or Perthes syndrome, is an uncommon clinical syndrome usually occurring after a severe crushing or compression-related injury to the chest preceded by deep inspiration. Symptoms and associated physical findings include subconjunctival hemorrhage, cervicofacial cyanosis resulting in a purple-blue neck and face discoloration, facial edema, vascular engorgement of the head, mucosal petechiae, and multiple ecchymotic hemorrhages of the face, neck, and upper chest. Cerebral hypoxia owing to hypoventilation is a life-threatening complication that can result in varying degrees of cerebral dysfunction. Sore throat, hoarseness, dizziness, numbness, and headaches are common. Pitting lower-extremity edema, hemoptysis, hemotympanum, hematuria, rectal bleeding, and transient visual loss can also be evident.⁷⁶ The diagnosis is made primarily from the history and physical examination, with chest radiographs being largely normal.

Prompt assessment of airway, breathing, and circulation—the overarching principles of trauma management—is critical, with special attention paid to re-establishing oxygenation and perfusion to ensure a successful outcome. Head elevation should be maintained at 30 degrees. If a patient survives the initial insult, the prognosis is excellent. Skin discoloration resolves within 3 weeks, but complete resolution of subconjunctival hemorrhage can take up to 1 month.

Pulmonary Contusion

The lung parenchyma fills a large portion of the chest cavity and lies close to the bony thorax, making it vulnerable to contusion. In fact, pulmonary contusion is the most common injury in blunt chest trauma.⁵⁶ The mechanism of injury usually involves a sudden deceleration injury, such as in a motor vehicle crash with the chest hitting the steering wheel, or in a blast injury or a fall from a great height. Although pulmonary contusions are generally associated with concomitant thoracic cage damage and other visceral injuries, they can occur isolated without evidence of rib fracture. Wagner and colleagues⁷⁷ have suggested that the pathophysiology of a pulmonary contusion is based on hemorrhage into

adjacent alveolar spaces rather than injury to the alveolar capillary wall itself.

Classic symptoms include dyspnea, tachypnea, hemoptysis, cyanosis, and hypotension. Physical examination can demonstrate inspiratory rales, and decreased breath sounds on the affected side. CT scan is the study of choice; it is more sensitive than radiography in detecting a pulmonary contusion. All patients with a pulmonary contusion should be observed on supplementary oxygen in a hospital setting, because of a tendency of their ventilatory status to deteriorate rapidly. By standard ATLS protocol, patients with significant hypoxia with PaO₂ less than 65 mm Hg and SaO₂ less than 90% despite oxygen supplementation should be intubated and undergo ventilation within 1 hour after injury. A conservative fluid management strategy should be undertaken; however, if large volumes of fluid are necessary for resuscitation of associated extrathoracic injuries, a pulmonary artery catheter should be placed.

As mentioned previously, patients with pulmonary contusions are at a high risk of respiratory insufficiency and secondary pneumonia because of the parenchymal damage and large systemic inflammatory response that accompanies this injury. The formation of a pulmonary contusion along with an Injury Severity Score greater than 65 have been identified as risk factors that have the greatest contribution to the development of acute respiratory distress syndrome.⁷⁸ The mortality rate from an isolated pulmonary contusion is low, but when combined with other severe injuries, it rises to as high as 50%.⁷⁹ Clinical factors predisposing to mortality after a pulmonary contusion include patient age, resuscitation volume, and severity of the pulmonary parenchymal injury as measured by PaO₂/FiO₂ (P/F ratio) at 24 and 48 hours after injury.⁸⁰ For patients requiring mechanical ventilation, little literature exists in predicting successful extubation. Reintubation after extubation occurs not infrequently, and it is associated with significant morbidity and mortality. A recent retrospective study identified both a P/F ratio of less than 190 or an Alveolar-arterial (A-a) oxygen gradient greater than 100 mm Hg as independent predictors of failed extubation after pulmonary contusion.⁸¹

Laryngeal Injuries

The larynx enjoys a position of relative protection in the neck shielded laterally by the sternocleidomastoid, posteriorly by the cervical spine, and from the front and above by the mandible. Blunt trauma to the larynx is therefore rare, but has a mortality rate reaching as high as 40%, with most patients dying at the trauma scene because of the nature of the injury.⁸² Death is due primarily to asphyxia from laryngospasm, hemorrhage from an associated major vascular laceration, or laryngeal concussion. Laryngeal trauma is suspected after motor vehicle crashes, hanging attempts, sporting blows such as in karate or soccer, and severe falls.

Signs and symptoms after laryngeal blunt trauma include hoarseness, pain, skin contusions, cervical emphysema, cervical neck crepitus, dysphagia, and upper airway obstruction. Subtle signs of dysphonia including easy fatigue during phonation, marked difficulty with

high-pitched and singing voice, and decreased phonation time can also occur. Diagnosis requires a high index of suspicion because many patients remain asymptomatic at an early stage of injury and minor symptoms may belie serious abnormalities. Furthermore, patients may be unable to supply critical aspects of the history and physical examination because of aphonia or intubation. Early diagnosis and appropriate therapy have a significant effect on the patient's condition later, especially regarding scar formation, ease of breathing, and voice quality.

After securing a patent and stable airway, transnasal flexible laryngoscopy is used for definitive diagnosis. Because the risk for laryngospasm and sudden airway obstruction is increased in the presence of a laryngeal lesion, preparations for emergency intubation or tracheostomy should be readied before performing endoscopy. Flexible laryngoscopy involves inspection for vocal cord mobility, mucosal edema, hematomas, tears, and arytenoid cartilage subluxation. CT scan is a sensitive diagnostic test for laryngotracheal injury, and it may be indicated despite normal flexible laryngoscopy. The status of the laryngeal skeleton can be determined more precisely with high-resolution CT scanning.

The decision to repair or observe laryngeal trauma is primarily based on the patient's respiratory distress and associated injuries. The presence of laryngeal fractures, air in the soft tissues, and extravasation of contrast material in the neck are helpful in assessing the extent of the injuries before surgical intervention. Immediate initial surgery is aimed at stabilizing the cartilaginous framework of the larynx and repairing the mucosa. For minor lacerations and abrasions of the larynx, observation is sufficient; however, for larger injuries, primary closure via a thyrotomy is the preferred management. Early and low tracheostomy is recommended for patients with endoluminal disruption of the larynx. Suboptimal results are found in patients with bilateral vocal cord paralysis, displaced cricoid fracture, and arytenoid subluxation.

Tracheobronchial Injuries

Tracheobronchial injuries are uncommon, but they usually occur after a high-energy impact and are associated with trauma to other vital organs.⁸³ According to an extensive review of all published tracheobronchial injuries since 1873, 59% of these injuries are due to motor vehicle crashes, 76% occur within 2 cm of the main carina, and 43% are located within 2 cm of the right main bronchus.⁸⁴ As the carina is in a relatively fixed position in the chest, it is more susceptible to shear forces from rapid acceleration and deceleration. Three potential mechanisms of blunt tracheobronchial disruption have been identified. The first and most common is due to a forceful anteroposterior compression of the thoracic cage, the so-called dashboard injury in which an unrestrained automobile occupant hyperextends and strikes their neck on the dashboard or steering wheel, producing a crushing injury of the cervical trachea. The second mechanism is a consequence of high airway pressures, whereas the third is due to rapid deceleration.

Typical clinical features include respiratory distress, dyspnea, and air leak. Hoarseness or dysphonia is also

common, occurring in up to 45% in some series. In patients with central airway injuries contained in the mediastinum, subcutaneous emphysema may be evidenced by crepitus. Injuries to the tracheobronchial tree that are in communication with the pleural space may progress to tension pneumothorax. If tube thoracostomy is required, an air leak is commonly observed with these injuries. A massive air-leak may be indicative of severe injury, and significant ventilatory volume loss can result when tube thoracostomy is maintained at high amounts of negative pressure. Persistence of an undiagnosed air leak is life threatening and can progress to respiratory insufficiency. On physical examination, the most common diagnostic signs are subcutaneous emphysema (35%-85%), pneumothorax (20%-50%), and hemoptysis (14%-25%).

The definitive diagnostic study of choice is flexible bronchoscopy. A careful bronchoscopic examination includes an inspection of the tracheobronchial tree documenting the site and extent of injury, including a withdrawal of the endotracheal tube in an intubated patient to diagnose proximal tracheal tears. A high level of suspicion is imperative for diagnosis because patients with tracheobronchial injuries occasionally exhibit normal clinical appearance and negative endoscopic findings. In fact, diagnoses of tracheobronchial injuries are often delayed, with the repair performed months and even years after the initial injury.⁸⁴ No statistically significant association was found between delay in treatment and successful repair of the injury, with 90% of patients undergoing successful surgical reconstruction more than 1 year after initial injury. Effective airway management consists of bypassing the lesion with endobronchial intubation to the healthy bronchus using a single-lumen or double-lumen endotracheal tube. Primary surgical repair of the injured airway is often necessary, with the decision to intervene based on the size of the lesion and the respiratory status of the patient. Simple, clean lacerations without much devitalized tissue can be repaired with simple, interrupted 4-0 Vicryl sutures (Ethicon, Cincinnati, OH). More severe injury may require lobectomy or pneumonectomy. The proximal one half to two thirds of the trachea is best seen using a low cervical collar incision, whereas the distal third of the trachea, the carina, and both the proximal right and left mainstem bronchi should be approached through a right thoracotomy. Prompt diagnosis and treatment generally lead to good functional recovery, but if tracheobronchial injuries remain undetected and untreated, late complications such as bronchial stenosis, recurrent pneumonia, and bronchiectasis can develop.

Great Vessels

The thoracic great vessels consist of the aorta and its major intrathoracic branches, the pulmonary arteries and veins, the vena cavae, and the azygous vein. By far the most lethal of these is the descending aortic injury, which accounts for as much as 40% of fatalities after blunt thoracic trauma with the majority of deaths occurring at the trauma scene.⁸⁵ Approximately 8000 people die annually in the United States from blunt thoracic aortic injury, and

it is second only to traumatic brain injury in terms of its overall mortality rate. Most of these deaths are due to free intrapleural aortic rupture. The site of injury is usually the isthmus, an area of the medial descending aorta near the ligamentum arteriosum where shear forces from rapid deceleration cause a tear at this point of fixation of the vasculature. Blunt thoracic aortic trauma is graded based on severity of injury. Type I injury involves an intimal tear, type II injury is seen as an intramural hematoma, type III injury involves pseudoaneurysm of the aorta, and type IV injury is evidenced by free rupture.⁸⁶ Again, a high index of suspicion in a patient who has suffered a high speed collision is critical because approximately half of the patients with contained aortic rupture have no external signs of trauma.⁸⁷

A plain chest radiograph has a 95% negative predictive value for identifying blunt traumatic aortic lesions, and thus represents an adequate diagnostic screening study.⁸⁸ The classic signs on plain chest radiograph (Fig. 7-7) as described by Kirsh and Sloan^{88a} include a widened mediastinum (>10 cm), loss of aortic knob contour, shift of the endotracheal tube and the trachea to the right, elevation of the left main stem bronchus, depression of the right main stem bronchus, shift of the nasogastric tube to the left, apical capping, first rib fracture, acute left-sided hemothorax, and a retrocardiac density. Of these, the finding that most reliably correlates with an aortic tear is loss of aortic knob contour. Still, traumatic aortic intimal injuries or pseudoaneurysms can evade plain radiographic detection. Spiral-CT scanning with angiography, which has 96.2% sensitivity and 99.8% specificity for blunt traumatic aortic abnormalities, has become the preferred confirmatory study in the algorithm of blunt aortic injury for hemodynamically stable trauma patients, and it is widely available. Conventional biplane contrast aortography should be considered despite previous negative studies if the clinical suspicion remains high, as 2% of patients with great vessel injuries are detected with this modality.⁸⁹ Those patients with an obviously widened mediastinum on radiography along with hypotension and

FIGURE 7-7 ■ Typical chest radiograph with widened mediastinum suggestive of aortic transection from decelerating blunt chest injury.

hemothorax are at high risk for imminent rupture of a contained aortic injury and can be taken to the operating room without further delay in obtaining confirmatory studies.⁹⁰

Once a contained aortic rupture is diagnosed, urgent management is required. Specifically, invasive monitoring and careful blood pressure and heart rate control with intravenous beta blockade followed by afterload reduction are indicated as a first step. A thorough neurologic examination to document any preoperative deficits is vital. If other life-threatening injuries, such as intra-abdominal bleeding, are detected in the primary or secondary survey, these are repaired first before the thoracic aortic injuries are addressed. If there is little time for preoperative studies, a TEE can even be performed during laparotomy to identify signs of blunt traumatic aortic injury. In the last decade or so, the four most dramatic changes in management of these patients have been nonoperative management, delay to definitive treatment, use of endovascular stenting for repair, and the increasing use of left heart bypass via centrifugal pumps in the operating room.⁸⁹

A subset of patients with contained aortic rupture including those with severe central nervous system injury, extensive burns, hemodynamic instability from other traumatic injuries, respiratory failure or those with small intimal defects are appropriately managed either nonoperatively or with a delayed operation.⁹¹ Mean arterial pressure should be maintained near 60 to 70 mm Hg in a manner similar to patients who have suffered an acute dissection of the descending thoracic aorta.⁸⁹ Although the length of time necessary for rigorous antihypertensive therapy is unknown, reports in a small series of patients followed serially by TEE have shown that complete resolution of small injuries (<20 mm) occurs in approximately 9 days (range, 3–19 days).⁹²

Since 1991, when the first endovascular stenting of the aorta was performed for an abdominal aortic aneurysm, interest in stent grafting as an alternative to traditional aortic surgery has surged. Preliminary experience is now accumulating from percutaneous positioning of endovascular stent grafts under angiographic guidance for blunt traumatic aortic lesions.^{93–96} An analysis of the available data has demonstrated this to be a safe and effective procedure.⁹⁶ This procedure has excellent technical success rates, averaging 96.3% with endoleak rates of 5.1% while maintaining low rates of complication, including overall and graft-related mortalities of 7.7% and 2%, respectively, and rates of paraplegia of 1.1%. More recent analyses including the RESCUE trial, a multicenter prospective trial, have demonstrated similar outcomes with an overall 30-day mortality of 8% and aortic-related mortality of 4%.⁹⁷ Coverage of the left subclavian artery with the endograft is reported in 39% to 48% of cases.^{86,97,98} Similar analyses of open repairs have demonstrated worse outcomes, with mean mortality of 14.7% and a rate of paraplegia of 3.3%. A meta-analysis from 2008 involving 17 retrospective studies comparing endovascular stent grafting to open repair demonstrated significantly lower 30-day mortality rates and postoperative paraplegia in those who underwent stent grafting.⁹⁹ In addition, length of hospital stay, transfusion requirement,

and need for additional surgical procedures have been shown to be lower among patients who undergo percutaneous stenting compared with open repair of traumatic aortic injuries.¹⁰⁰ As the technology progresses and the grafts and their delivery systems become easier to use, long-term studies, including randomized, prospective trials evaluating the durability and efficacy of this approach, will be warranted.

The open surgical approach uses a fourth interspace left posterolateral thoracotomy. Proximal and distal control is obtained, with care taken to avoid injury of the recurrent laryngeal and vagus nerves and the thoracic duct. There has been considerable controversy over more than two decades between proponents of the use of clamp-and-sew techniques versus unloading the heart proximally and shunting the blood distally. Traditional arguments against the use of left heart bypass with passive shunts included the need to heparinize a trauma patient with associated injuries and the lack of data demonstrating decreased neurologic injury with passive shunting. Convincing evidence is accumulating, however, demonstrating the benefits of left atrial to femoral shunting via a centrifugal pump. Many of these systems do not require heparin, and there is a growing body of literature demonstrating low rates of paraplegia and mortality.^{101–103} Although prolonged clamp times and the increasing complexity of the repair are associated with rising paraplegia rates, another important predictor of paraplegia has been the occurrence of upper body hypotension during surgery. Left atrial-to-femoral shunting during and immediately after clamping of the aorta allows strict control of upper body blood pressure. In fact, results from a review of a 30-year experience of blunt traumatic aortic rupture remarked on the gradual evolution in clinical surgical technique from “clamp-and-sew” to “passive shunt” to “heparin-less partial bypass.”¹⁰³

Blunt Cardiac Injuries

For decades, the term *cardiac contusion* has been used to describe a wide clinical spectrum of conditions thought to be associated with blunt injury, ranging from elevation of cardiac enzymes to complex intracardiac defects or rupture. This term should now be omitted entirely because of its inconsistent clinical descriptions, and because it offers little in terms of its ability to dictate therapy or predict outcomes.¹⁰⁴ In keeping with the system of assigning trauma scores in the acutely injured patient, a new classification for blunt cardiac injury has been developed and is currently in use at major trauma centers (Table 7-2).¹⁰⁵

Although frequently highlighted in the literature, only a few patients require intervention for blunt cardiac injuries. These injuries are usually a result of high-speed motor vehicle crashes, falls from heights, crush and blast injuries, or direct violent assaults. Most motor vehicle-related deaths, however, are related to blunt injuries of the heart and great vessels. Mechanisms of decelerating cardiac trauma include compression by the sternum, impingement between the sternum and vertebral bodies, and increased venous return from crushing lower extremities injuries resulting in rupture of the cardiac chambers

TABLE 7-2 Blunt Cardiac Injury Terminology and Scoring System

Blunt Cardiac Injury	Trauma Score
No ECG, physiologic, or anatomic abnormality	1
Minor ECG abnormality	1
Major ECG abnormality	1
Cardiac enzyme elevation	1
Free wall hematoma	2
Septal hematoma	2
Septal defect	2
Valvular insufficiency	4

ECG, Electrocardiogram.

from overdistention. Although it was once thought that sternal fractures were associated with a high incidence of blunt cardiac injuries, ironically, there has been no proven association between the two. The incidence of these injuries, however, ranges from 10% to 70%, depending on the diagnostic modality and criteria used.

Clinically, there are few signs and symptoms that are specific for blunt cardiac injuries. Chest wall abnormalities may or may not be present. Chest pain is common and is usually related to external injuries, and occasionally patients will describe anginal-type pain, unrelieved with nitrates. One relies on the mechanism of injury, external chest trauma, and a high index of suspicion to determine whether a more aggressive workup of cardiac trauma is warranted. With more significant blunt injuries, hemo-pericardium can develop. Progression to cardiac tamponade is life threatening and may be signified by Beck's triad, consisting of decreased heart sounds, hypotension, and elevated central venous pressure as evidenced by jugular venous distention. In addition to decreased cardiac sounds, auscultation may reveal a murmur stemming from septal or valvular defects.

To date, there is no diagnostic gold standard for blunt cardiac injury. Although no direct correlation exists, one should have a heightened suspicion of blunt cardiac injury when a sternal fracture is present. An electrocardiogram (ECG) should be performed on all patients in whom blunt cardiac injury is suggested, but practically all trauma victims eventually undergo electrocardiography on admission. New-onset tachyarrhythmias, especially sinus tachycardia, are the most common findings on admission ECG, and this initial ECG is the best indicator of blunt cardiac injury.^{106,107} Otherwise, the ECG is unreliable unless ST elevation is present.

Levels of creatinine kinase-myocardial bands and troponin have become part of the standard laboratory evaluation tests, but like the ECG are limited by the lack of a precise threshold for the diagnosis of a blunt cardiac injury. In the patient with musculoskeletal trauma, the significance of the creatinine kinase-myocardial band level remains questionable. Recently, cardiac troponin I and T levels were found to be highly sensitive for myocardial injury and useful in the stratification of patients

at risk for complications.¹⁰⁸ Alternatively, in a single institution study of the diagnostic utility of troponin I and troponin T, the specificities of elevated troponin I and T levels for myocardial contusion were found to be 97% and 100%, respectively, whereas the sensitivities of troponin I and T were 23% and 12%, respectively.¹⁰⁹ Thus, debate still exists regarding the utility of an abnormal ECG, echocardiogram, and cardiac enzyme levels in predicting myocardial injury, and how these affect therapy, decision making, and outcomes.¹⁰⁵

Echocardiography remains the best diagnostic tool for detecting injuries, wall motion abnormalities, effusions, valvular or septal defects, and particularly chamber rupture.¹¹⁰ This should be performed in all patients with an abnormal ECG or who are hemodynamically unstable. An attempt at transthoracic imaging should be made first, but if insufficient data are rendered, the transesophageal route should be undertaken. Because of their anterior location, the right atrium and ventricle are the most frequent chambers injured, followed by the left atrium and left ventricle. Mortality from one chamber rupture is 60%, and universally fatal if two are involved.

Radionucleotide imaging can be helpful in documenting cardiac defects and predicting complications; however, it might not be practical in the acutely injured patient, and it cannot differentiate new injuries from chronic pre-existing disease. Furthermore, in the presence of a normal echocardiogram, this test is of little utility because it offers little direction in terms of management. Multiple gated acquisition scans are recommended, however, if the ECG is abnormal and there is evidence of ventricular failure.¹¹¹

The recommended observation and treatment options depend on the suggestion of blunt cardiac injury and any associated diagnostic test abnormalities. As stated previously, the presence of a sternal fracture does not predict blunt cardiac injury, and monitoring is not necessarily indicated. Patients with an abnormal ECG (e.g., arrhythmia, ST changes, ischemic changes, heart block) should be admitted for continuous ECG monitoring for at least 48 hours. Conversely, a prolonged hospital stay with cardiac monitoring is no longer required if the initial ECG and echocardiogram are normal, and most patients are discharged after 12 hours. The younger patient rarely develops cardiac complications even when there are mild ECG, echocardiogram, and enzyme abnormalities. However, in older patients with known cardiac disease, appropriate cardiac monitoring is necessary when injury is associated with hemodynamic instability, multisystem trauma, or ECG changes or when the patient is to undergo general anesthesia. In addition, in the hemodynamically unstable patient with concern for myocardial injury, and with multiple potential reasons for instability, consideration should be given to pulmonary artery catheter placement.

Operative intervention is required in 5% to 10% of patients with nonpenetrating cardiac injuries. Chamber ruptures are usually isolated events. Repair is typically done with simple cardiorrhaphy and a running suture, usually 4-0 polypropylene. Pledgets are required for right and left ventricular repairs. Valvular injuries have been reported in the aortic, mitral, and pulmonary positions.

Cardiopulmonary bypass is required for left-sided repairs. Occasionally, valve resuspension or chordae reattachment can be done, but most injuries require valvular replacement. Ventricular septal defects can present either acutely or after several days of progressively worsening congestive heart failure. Operative repair is required for larger defects and for those associated with a left ventricular aneurysm. Pericardial tears with associated cardiac herniation are uncommon and have been described in the left, right, and midline diaphragmatic locations. With small tears and complete herniation, death is almost immediate. Larger tears manifest as intermittent positional hypotension, and they are usually found at the time of exploration for other injuries. Direct suture closure is required. Patch closure is rarely needed. Finally, arteriovenous fistula or thrombosis is an uncommon complication involving the coronary vessels. The diagnosis is usually made after the appearance of long-term sequelae, including left ventricular pseudoaneurysm, cardiac failure, embolism, or arrhythmias. Surgery is directed at the specific complication.

Diaphragm

With the advent of modern high-speed transportation, traumatic diaphragmatic injury appears to be a disease in evolution. Injury to or rupture of the diaphragm because of blunt torso trauma is seen with increasing frequency. In North American series, the prevalence of diaphragmatic rupture among blunt trauma victims ranges from 0.8% to 8%, with a slight predisposition for the left side.¹¹² Because of greater awareness, routine use of chest roentgenograms in the initial evaluation of trauma patients, availability of minimally invasive techniques, and improved access to modern trauma care systems, surgeons are increasingly facing the diagnosis and management of diaphragmatic injuries. Despite these advances, persons with traumatic diaphragmatic injury suffer a higher mortality rate in comparison with blunt trauma patients without this injury.

Diaphragmatic injuries can be classified according to the mechanism of injury, side involved, unilateral or bilateral location, clinical sequelae following the onset of injury, and severity of the anatomic disruption. The latter has an important practical application in predicting outcome and associated visceral injury, because these patients with diaphragmatic injuries are at risk for severe multisystem trauma. Blunt diaphragmatic rupture occurs mainly from high-speed motor vehicle crashes when the rapid deceleration results in a nonuniform pressure load on the inflexible central tendon. In particular, lateral impact to the torso is three times more likely to rupture the diaphragm than from a frontal direction. Because the diaphragm is buffered by the liver on the right, a larger percentage of injuries occur on the left; bilateral injuries occur in less than 3% of all cases. Compared with the left side, patients with right hemidiaphragm ruptures tend to have worse increased multiorgan involvement, more hypovolemic shock, lower Glasgow Coma Scale score, and higher mortality. Bilateral ruptures, including those involving the pericardium, are rare in patients who reach the hospital alive.

Diaphragmatic injury or rupture can also be classified by the time of presentation. Three clinical phases follow the onset of traumatic diaphragmatic injury: acute, latent, and obstructive phases.¹¹² The acute phase begins with the original trauma and ends with the apparent recovery from other injuries, and thus may mask the diaphragm injury. Most patients (60%) have nonspecific pain in the left upper quadrant or lower thoracic or shoulder pain. Others have severe acute symptoms of dyspnea, hypotension, or cyanosis owing to compression of the lung and mediastinal shift from the herniated organs.

In the latent or interval phase, symptoms are variable and nonspecific as the patient compensates for having intrathoracic abdominal contents. The symptoms may mimic other disorders such as peptic ulcer disease, biliary colic, partial bowel obstruction, and chronic obstructive pulmonary disease. Symptoms of intermittent bowel obstruction aggravated by eating or lying on the left side are relieved by belching, vomiting, or flatus.

Finally, the obstructive phase can occur at any time when bowel obstruction occurs following incarceration of herniated viscera. This can lead to necrosis if diagnosis and treatment is further delayed. In one series, the onset of the obstructive phase ranged from 20 days to 28 years, but 90% usually present with strangulation within 3 years. These patients exhibit symptoms consistent with slow progressive herniation of stomach and bowel contents into the chest cavity. These include nausea, vomiting, abdominal pain, and obstipation, and they can ultimately lead to respiratory distress, shock, obstruction, strangulation, and signs of viscus perforation.

The diagnosis of acute diaphragm injury or rupture is a clinical challenge, especially in patients who do not have obvious indications for emergent exploration. Because diaphragmatic defects do not heal and can eventually lead to a latent visceral herniation, delayed diagnosis can be catastrophic. With previous blunt trauma, intermittent bowel obstruction without a previous abdominal incision should raise the possibility of diaphragm disruption. Findings on physical examination such as paradoxical motion of the left upper abdominal quadrant, decreased intercostal retraction, decreased breath sounds, or shifting of cardiac sounds should raise suspicion. Diagnosis in the latent phase can be also difficult, particularly with right-sided injuries, because of vague symptoms. Often, patients might not recall any previous history of trauma, and physical examination may reveal bowel sounds over the chest.

Plain chest films are the initial screening test of choice, but up to 75% of them will be non-diagnostic. Findings suggestive of a diaphragm defect include an indistinct costophrenic angle, elevated or indistinct hemidiaphragm, air fluid levels in the chest, and abnormal pleural densities (Fig. 7-8). Right diaphragm injuries are rarely detected. CT and ultrasonography are often positive when there is frank visceral protrusion into the chest. The development of high-resolution CT has improved the sensitivity of this diagnostic modality.

For left-sided ruptures, the diagnosis is usually made if a nasogastric tube passed into the stomach is seen in the hemithorax, or if an upper gastrointestinal contrast series reveals a narrowing of the obstructed stomach or

FIGURE 7-8 ■ Chest radiograph following blunt thoracic trauma suggestive of left diaphragmatic rupture.

FIGURE 7-9 ■ Upper gastrointestinal barium study delineating stomach and small bowel contents years after blunt decelerating injury.

bowel segment above the diaphragm (Fig. 7-9). If an aortogram is performed for other reasons, the splenic or gastric vessels may be seen above the diaphragm. Although radionuclide scanning, fluoroscopy, and magnetic resonance imaging are highly accurate in the diagnosis of blunt diaphragmatic rupture, the use of these modalities in multiply injured, unstable patients is impractical.¹¹³ Right-sided ruptures may show a total or partial (“mushroom” projection) liver herniation with or without associated bowel contents.

Minimally invasive surgery for the evaluation of the diaphragm and other structures can be performed effectively while avoiding the morbidity of an open procedure. Routine laparoscopy is recommended to evaluate occult diaphragmatic injuries in stable patients with left thoracoabdominal penetrating injuries who otherwise have no indications for an open operation. Among these patients, up to one quarter will have diaphragmatic injuries that were missed during the trauma radiographic workup.¹¹⁴ These diaphragmatic injuries can be repaired at the time

of diagnosis during laparoscopy. In patients with previous abdominal surgery, a video-assisted thoracic surgical approach may be preferred to evaluate and repair the diaphragm once intra-abdominal injuries have been ruled out.

The surgical approach to repair acute diaphragmatic injury or rupture depends on the mechanism of injury, condition of the patient, and time of presentation. Shock should be corrected, and a nasogastric tube should be placed to decompress the stomach. After immediate life-threatening injuries are addressed, the diaphragm can be inspected thoroughly for defects. Even the smallest defects should be closed. Laparotomy can be performed first to explore the abdomen for other injuries, but diaphragmatic defects can be repaired from either the abdomen or chest. When both cavities need to be explored, separate incisions are favored over a continuous one because of the higher morbidity.

In patients who require emergent laparotomy for suspected intra-abdominal injuries, thorough inspection of both hemidiaphragms is mandatory, regardless of the direction of the blunt impact. Diaphragmatic rupture resulting from blunt trauma should be approached through a laparotomy because of the high incidence of simultaneous intra-abdominal solid organ injuries. Similarly, hemodynamically stable patients with diaphragmatic injury confirmed with noninvasive imaging or by laparoscopy should undergo laparotomy to rule out occult intra-abdominal injuries.

In contrast to the acute presentation, many surgeons prefer a thoracotomy approach for injuries and hernias that manifest in a delayed fashion. Although this approach provides excellent exposure to divide the adhesions between the trapped viscera and lung parenchyma, a transabdominal approach may be preferable for left hemidiaphragmatic hernias in which segments of small or large bowel may have to be resected and anastomosed. However, a thoracotomy approach should be used for all right-sided diaphragmatic defects, regardless of the timing following initial injury.

The herniated viscera is first carefully reduced and returned to the abdominal cavity. The preferred method of closure of the diaphragmatic defect is by interrupted full-thickness nonabsorbable 0 or no. 1 sutures. Adhesions are taken down, the lung is decorticated, and if necessary, the diaphragm is loosened from the lower rib to take tension off the repair. For the chronic rupture, a splenectomy may need to be performed, followed by enlargement of the defect in order to facilitate repair. Finally, on the rare occasion in which the tissue loss is extensive, closure of the defect can be achieved with fascia lata, biologic material such as bovine pericardium, or synthetic material.

Mortality and morbidity in patients with acute diaphragmatic injuries differ considerably from those with a delayed presentation.¹¹⁵ In the former, multiorgan trauma is usually present, and thus irreversible shock and head injury are most often cited as the causes of early death approaching 40%. With strangulated bowel, the rate goes to 80%. When these injuries are isolated and repaired adequately, complications are rare, and usually pulmonary in nature. With the chronic type, sepsis and

multisystem organ failure are the usual causes of mortality. In the presence of bowel strangulation and gangrene, a much higher postoperative mortality (66%) and morbidity (80%) is encountered compared with patients with an uncomplicated operative approach.

Esophagus

Blunt and penetrating trauma to the esophagus are both rare because of the relatively protected location of the thoracic esophagus in the posterior mediastinum.¹¹⁶ Blunt esophageal trauma is much rarer compared with penetrating injuries, but when it occurs, it is more commonly the result of a direct blow to the cervical region, such as hitting the steering wheel during decelerating motor vehicle crashes or from padded objects such as boxing gloves. Simultaneous rupture of the esophageal wall and adjacent membranous trachea wall can occur if both are compressed between the sternum and vertebral body, resulting in fistula formation. It is estimated that one third of all tracheoesophageal fistula have this etiology, second only to iatrogenic causes. Other blunt force injuries include manual compression during cardiopulmonary resuscitation (up to 12% incidence found during autopsy) and the Heimlich maneuver.

A Boerhaave-like rupture injury can occur from increased intraluminal pressure with a closed glottis and increased intra-abdominal pressure. This usually occurs just above the esophagogastric junction, with rupture into the left pleural space where there is less protection by the pleural lining. Mortality is high, not because of the severity of the injury but because of the delayed diagnosis and ensuing complications. Other etiologies of barotraumas include blast injuries and introduction of high pressure gases (e.g., fire extinguisher discharges, eruption of carbonated drinks, and gas ingestions from biting of inner tubes). Finally, localized wall or long segment necrosis has been described despite its rich blood supply, as the arterial inflow is torn away from severe blunt trauma.

Blunt esophageal injuries are often difficult to diagnose early, because of the multisystem trauma issues and lack of recognition. Patients may exhibit signs and symptoms of esophageal leak: subcutaneous air, pneumomediastinum, aspiration (from fistula formation), mediastinitis, hypotension, tachycardia, and sepsis in the more advanced cases. Diagnosis can be made from a contrast swallow study, but in the compromised trauma patient, this usually cannot be performed. A CT scan in some cases may detect small leaks into the neck or mediastinum not seen on contrast esophagography. Esophagoscopy is helpful, and it has been reported to have higher sensitivity than contrast studies.¹¹⁷

With free perforation or fistula formation, early surgical repair is advocated. Conservative medical therapy (broad-spectrum antibiotics, close observation, parenteral nutritional support) is chosen only in selected patients when the leak is minimal and contained and the patient's condition is clinically stable. Approaches are dictated by the level of involvement. Cervical incisions usually suffice for defects in the neck, but may require exposure with an upper sternal split for the thoracic inlet.

A right thoracotomy may be required for the upper thoracic third of the esophagus, whereas the left side is preferred for those just above the esophagogastric junction. The surgical principles are like those of other benign perforations of the esophagus. The edges are trimmed of devitalized tissue and closed in multiple layers. A tissue flap is added to buttress the repair. When a fistula is taken down, the esophageal and tracheal openings are closed primarily, and the suture lines must be separated by a tissue flap to prevent reformation. These flaps include intercostal muscles, strap muscles, mediastinal thymic fat, pericardium, and diaphragm. A tracheostomy has been advocated to help protect the tracheal suture line. For patients with delayed diagnosis and in those who remain in hemodynamically unstable condition, esophageal diversion rather than primary repair may be required.

Extensive necrosis of the esophagus is associated with a much higher mortality rate. When suggested, the diagnosis is made with endoscopy noting the mucosal ischemic changes. In these circumstances, emergency esophagectomy and proximal diverting esophagostomy is required, with reconstruction of gastrointestinal continuity performed at a later date.

PENETRATING TRAUMA

Stab Wounds versus Firearm Injuries

The evaluation and management of penetrating trauma to the thorax is best broken down by anatomic distribution.¹¹⁸ This includes the chest wall, the great vessels and other major vascular structures, the trachea and major bronchi, the lung parenchyma, the heart, the esophagus, and the diaphragm. Each of these structures can be injured individually and in combination with other intrathoracic or extrathoracic structures. The evaluation of thoracic injury requires a systematic approach founded on anatomy to rapidly identify injury and initiate therapy. Penetrating injuries to the chest can be both subtle and dramatic in presentation. Paramount in the management is a rapid assessment and evaluation of the patient's severity of injury. Patients who appear "stable" can deteriorate rapidly and can become acutely moribund through tension pneumothorax or pericardial tamponade as well as massive intrathoracic hemorrhage.

Once the initial primary survey has been performed, the patient's disability should be evaluated, specifically with determination of the location and mechanism of penetrating injury. Puncture wounds can be small and easily missed. The patient must be rolled and completely exposed with close inspection of critical areas, such as the axilla. Central wounds and peripheral wounds have different implications. Lower thoracic versus upper thoracic wounds suggest potential injuries to neck structures and abdominal structures, respectively, in addition to a thoracic injury. Stab wounds differ from gunshot wounds in their potential depth of penetration and degree of damage to surrounding organs. Knife wounds are limited to the direct tract of the blade and impart only the kinetic energy transfer to surrounding tissue that is manually produced. Gunshot wounds, however, impart kinetic

energy to the surrounding tissue produced by the mass and velocity of the bullet (Kinetic energy = $\frac{1}{2} \times \text{Mass} \times \text{Velocity}^2$). In addition to injury along the direct wound path, radial injury is produced by the kinetic energy transferred to the surrounding tissue. Wounds can be classified as “low energy transfer” or “high energy transfer.”¹¹⁹ In general, handgun wounds produce low-energy-transfer injuries, and high-velocity rifles produce high-energy-transfer injuries. These issues should be evaluated rapidly and considered in the primary survey.

Chest Wall Injury

The chest wall provides a rigid support and protection to the contents of the chest. Injuries that are limited to the chest wall itself rarely require surgical intervention. These injuries include intercostal vascular injuries that can produce hemothorax and injuries to the internal mammary artery. These injuries are usually managed easily with ligation or electrocautery. Blast injuries caused by high-velocity missiles or shotgun injuries can result in major tissue loss of the chest wall, including soft tissue and the bony thorax. These injuries can be initially covered with adhesive sterile drapes or a soft Esmarch covering with placements of chest tubes inside the thorax to achieve lung inflation and control any air leak. Definitive coverage of the defect using rotational flaps or free flaps of latissimus muscle, pectoralis major, serratus anterior, or omentum can be performed at a later time.

Tracheal and Bronchial Penetrating Injuries

Although penetrating injuries to the trachea and major bronchi are rare, encompassing 1% to 2% of thoracic trauma admissions, the nature of these injuries is serious, and these patients often present with respiratory distress.¹²⁰ Following the principles of ATLS, airway management and control of breathing with endotracheal intubation for adequate ventilation is the first role in management. Although a vast majority of blunt injuries to the trachea occur with 2.5 cm of the carina, almost three quarters of penetrating tracheobronchial injuries involve the cervical trachea.¹²¹ The need to establish a surgical airway in more proximal laryngotracheal injuries should be anticipated and performed without hesitation should oral endotracheal intubation prove difficult or impossible. In one series, almost half of these injuries required surgical airway.¹²² Cricothyroidotomy or tracheostomy is unlikely to provide any advantage over endotracheal intubation in more distal tracheal or bronchial injuries. Gunshot wounds are the most common cause of central airway injury although stab wounds are also possible. Stab wounds that injure the airway are more likely to be in the neck.^{123,124}

Signs of airway injury include subcutaneous emphysema, hemoptysis, pneumothorax, and air leak upon chest tube insertion. Plain films may reveal pneumothorax, pneumomediastinum, atelectasis in an underinflated lung or lobe, or the “falling lung sign of Kumpe” if the lung has collapsed away outward and downward (rather than inward and upward) from the hilum.¹²⁵ Adequate

ventilation may prove challenging in the setting of a tracheal or hilar injury. Intrapleural injuries produce pneumothorax and should be treated with immediate chest tube insertion. Massive air leak should raise the suspicion of a major bronchial injury but lack of air leak in the chest tube drainage system does not rule out the presence of injury. Bronchial edges may be approximated to seal a leak. A clot obstructing the bronchus may prevent air egress from the area of injury. Intubation and bronchoscopy are the first steps in managing a suspected bronchial injury. Extrapleural or mediastinal injury might not manifest as pneumothorax, but instead as massive mediastinal air or subcutaneous emphysema.

Flexible bronchoscopy should be performed and the complete tracheobronchial tree examined, as this remains the gold standard for diagnosis. If a proximal tracheal injury is suggested, the patient can be intubated over a bronchoscope to inspect the airway fully. Fiberoptic intubation can be performed with the patient awake, and sedation and paralysis are initiated after the airway has been established. Proximal tracheal injuries are best managed initially with intubation distal to the area of injury and control of the air leak. Injuries to the mainstem bronchi can be more challenging to manage initially. Bronchial blockers or Fogarty catheters are used to occlude the side of the injury, to control massive air leak, and to prevent inadequate ventilation. Double lumen endotracheal tubes should be used if possible for selective ventilation of the lung on the side of the uninjured airway. Injuries to the airway can result in significant amounts of blood in the tracheobronchial tree and can contribute to problems with ventilation. Aggressive toilet bronchoscopy must be performed with lavage of the airway until clear.

Surgical management of tracheal or bronchial injuries follows the same principles of tracheobronchial resection and repair used for neoplasms (Fig. 7-10). Proximal tracheal injuries can be managed through a cervical collar incision or an upper sternal split. More distal tracheal injuries are best approached through a right posterolateral thoracotomy incision. Bronchial injuries are best

FIGURE 7-10 ■ Resection and repair after gunshot wound to the cervical trachea. (From Lee RB: Traumatic injury of the cervicotracheal trachea and bronchi. *Chest Surg Clin N Am* 7:300, 1997.)

approached through posterolateral thoracotomy to the side of the injury; the exception is that for proximal left mainstem bronchial injuries and carinal injuries, the right side is the optimal approach. On initial entry, control of the hilum with isolation of the pulmonary artery and veins is the initial goal. Unsuspected vascular injury may be present, and proximal control of these vessels is critical. Umbilical tape can be used, and tourniquets can be draped loosely around the vessels to control bleeding rapidly and to mitigate the potential for air embolus. The airway is then dissected out, débrided, and repaired using interrupted absorbable sutures in the standard manner of sleeve resection or bronchoplasty. Tension-free technique of airway repair should be performed. Mobilization of the airway should be adequate to decrease tension but not compromise blood supply, which usually runs along the membranocartilaginous junction. Large defects in the airway may require lung resection, although lung sparing techniques should be attempted. Injury to a lobar bronchus might be best treated with standard or sleeve lobectomy. Pneumonectomy should be avoided at all costs given the extremely poor outcomes of patients requiring pneumonectomy for trauma.^{126,127} Postoperative care should include aggressive pulmonary toilet and attempts to wean from positive pressure ventilation as soon as possible. Aggressive bronchoscopy should be performed to keep the airway clear of secretions and prevent atelectasis. As in all thoracic surgery, early ambulation is critical.

Pulmonary Injuries and Hemothorax

Pulmonary injuries secondary to penetrating trauma can vary from small pleural or parenchymal lacerations from a stab wound to massive pulmonary injury secondary to a gunshot wound. The initial evaluation in addition to the ABCs should include a routine chest radiograph in the stable patient. Physical exam to detect hemothorax and hemopneumothorax can be unreliable, particularly in a patient who is stable with minimal symptoms. Asymptomatic patients with a normal chest x-ray can be safely observed and discharged after an appropriate time interval.¹²⁸ This time interval is a subject of debate although a serial chest radiograph at 6 hours seems to be a reasonable time period to pick up a delayed hemothorax or pneumothorax. In fact, of all thoracic trauma patients, less than one fifth will have injuries that necessitate placement of a chest tube to manage their injuries.¹²⁹

Local wound exploration and tractotomy of thoracic wounds is not recommended due to the potential to cause a pneumothorax and contaminate the pleural space. Tube thoracostomy should be performed in all patients with a pneumothorax or findings of pleural fluid resulting from penetrating trauma. We recommend this even if the pneumothorax is small or the fluid appears minimal. Tube thoracostomy allows monitoring of bleeding and any potential need for thoracotomy should the bleeding prove to be significant. In addition, it prevents accumulation of clot that might later prove difficult to drain and require decortication. Patients with minimal chest tube output and no air leak can have the chest tube removed on the first hospital day and be discharged. Persistent bleeding mandates thoracotomy or video-assisted tho-

racic surgery (VATS). Massive bleeding on chest tube insertion should be treated with emergent thoracotomy with no attempt to use thoroscopic techniques.

Most pulmonary lacerations do not require surgery and can be treated with tube thoracostomy. In fact, in a series of 755 penetrating injuries to the chest, more than half of which were gunshot wounds, only 8% required thoracotomy.¹³⁰ Drainage of the pleural space with reestablishment of pleural apposition can tamponade what is generally low pressure venous bleeding and serves to seal an air leak. Even high-velocity war-related injuries usually respond to conservative measures of chest tube drainage, antimicrobial therapy, and wound care.¹³¹ Large air leaks on chest tube insertion should raise the concern for bronchial injury and require further evaluation with prompt bronchoscopy and possible thoracotomy.

If thoracotomy is necessary, the general rule is to spare as much lung as possible and to avoid anatomic resection. A posterolateral thoracotomy is performed to gain access to the hilum of the lung. Lung isolation is obtained expeditiously with a double lumen tube or bronchial blocker. This isolation serves to induce atelectasis in the damaged lung so as to perform a tension-free repair or resection of the lung and to help prevent air embolus. As in all thoracotomies for penetrating thoracic trauma, the hilum and pulmonary vessels are controlled early with umbilical tapes or vessel loops to allow rapid vascular control should an unsuspected central injury be present that was previously unnoticed. Nonanatomic resections are performed whenever possible. Stapling devices allow for a generous margin around the area of injury during resection of damaged tissue. Hematomas should be treated with a broad margin and vascular load to the stapler to achieve hemostasis. Staple lines can be oversewn to reinforce the region and to support hemostasis if the staple line was not adequate to stop bleeding. Persistent bleeding from deep missile injuries can be opened and exposed by inserting the anvil of the linear stapler into the tract and firing the device to perform a "tractotomy." If there is extensive tissue loss, anatomic resection of an injured lobe may be necessary. The literature shows that mortality is directly correlated to the extensiveness of the procedure, ranging from 13% with tractotomy to 50% with pneumonectomy in one series.^{132,133} Multiple studies have identified extent of resection and blunt injury mechanism as independent predictors of mortality.^{133,134} Pneumonectomy is to be avoided and performed only if all other measures to salvage the lung have been exhausted. Anatomic resections require some form of bronchial stump coverage given the contamination of the pleural space and risk for subsequent infection and bronchopleural fistula.

The timing of thoracotomy for thoracic hemorrhage after trauma has been widely discussed. Recommendations have been made to perform thoracotomy if there is an initial chest tube output greater than 1500 mL or if there is greater than 250 mL/hr chest tube output for 3 consecutive hours after its placement.¹³⁵ Slightly differing amounts of chest tube outputs have been used as guidelines for operative intervention for ongoing bleeding. However, one recent multicenter trial showed that mortality linearly increased as the total amount of chest tube

output increased and used 1500 mL total chest tube output within the first 24 hours after injury as a recommendation to intervene surgically.¹³³

Cardiac Injuries

Penetrating injuries to the heart are a significant challenge to manage.¹³⁶ They are one of the leading causes of death in urban trauma, accounting for a high rate of prehospital death and in-hospital mortality. Most patients who sustain cardiac injuries die before reaching the hospital, and almost two thirds of patients with penetrating cardiac injuries have no vital signs upon arrival to the trauma bay. Reported mortality for these injuries varies from one series to another. What is clear is that the mechanism of injury clearly influences survival. In general, these injuries are one of two types: stab or gunshot wounds. Penetrating cardiac injuries secondary to blunt trauma that produces fragments of fractured rib or sternum are rare. Gunshot wounds carry higher mortality than knife wounds do because stab wounds will often seal themselves quickly, and the resulting cardiac tamponade can allow these patients time for definitive management. Ballistic trauma, however, produces much larger, irregularly contoured wounds that result in hemorrhage without tamponade because the pericardial sac is no longer intact. The management of patients in extremis or near extremis with penetrating injuries to the heart consists of airway management with endotracheal intubation, the establishment of intravenous access capable of massive volume resuscitation, and immediate thoracotomy through a left anterolateral approach. This approach allows rapid exposure of the heart and the ability to relieve tamponade from hemorrhage. In addition, it allows the surgeon the ability to perform open cardiac massage, control cardiac injuries, cross clamp the descending aorta to preferentially perfuse the brain and coronaries, and allow volume resuscitation in the setting of exsanguination and shock.

The patient's physiologic condition at the time of presentation significantly affects outcome. The clinical features of a patient with a penetrating cardiac injury depend on the degree of pericardial tamponade and the amount of blood loss. Coronary artery injuries are rare but can cause ischemia resulting in hemodynamic instability from myocardial dysfunction. One prospective study of 105 patients with penetrating cardiac injury showed that patients in physiologic collapse on presentation that required emergent ED thoracotomy had a mortality rate of 86%, whereas those who were stable enough to be transported to the operating room for thoracotomy had a 26% mortality.¹³⁷ The need for aortic cross-clamping was a significant predictor of poor outcome (89% mortality), which was likely due to the poor physiologic condition of these patients on presentation. Survival from stab wounds (65%) in this study was significantly higher than for gunshot wounds (16%). More recent studies have identified ambulance transportation, stab wound versus gunshot wound, sinus tachycardia, and the presence of vital signs upon arrival to the trauma bay as predictors of survival following ED thoracotomy following penetrating cardiac trauma.¹³⁸

All penetrating cardiac injuries have the potential for mortality, and it is not clear that the particular area of the heart that is wounded carries a worse prognosis. More than one third of all penetrating cardiac trauma results in isolated right ventricular injury, whereas one quarter of patients will have isolated left ventricular injury.¹⁰¹ In addition, 30% of patients will have multichamber injuries. Ventricular injuries, particularly right ventricular injuries, seem to be more common given its more anterior location. The left and right atrium are less commonly injured given their smaller size and more protected location. Intrapericardial great vessel injuries also are unusual. Although it is not possible to say that one anatomic location of injury portends a worse outcome, it does appear that multichamber and complex cardiac wounds have a worse prognosis than a single chamber injury does.

Although many cardiac injuries are obvious on presentation, such as a patient in hemodynamically unstable condition with a penetrating injury in proximity to the heart, diagnostic evaluation is necessary for other patients that are in stable condition and may harbor occult cardiac injury. These injuries must be identified. Even small knife wounds to the heart are unlikely to seal spontaneously and will eventually result in tamponade. The hole in the pericardium produced by the knife or projectile will frequently seal with clot or pericardial fat. Blood from the heart will accumulate and impinge on the filling of the atrium and ventricle. The incidence of occult injury has been reported to be as high as 20% in asymptomatic patients with penetrating stab wounds to the chest.¹³⁹ A workup is indicated in patients with penetrating precordial, right- or left-sided chest wounds as well as thoracoabdominal and abdominal wounds. Tachycardia is usually the earliest sign of decreased preload and impending tamponade. As the pericardium fills with blood, elevated filling pressures become necessary to overcome the compressive effects of accumulating pericardial pressure and to maintain delivery of blood to the right and subsequently left heart. This results in the clinical findings of distended neck veins and pulsus paradoxus (decrease in systolic pressure with inspiration). These signs can be subtle and difficult to detect in a noisy ED or in a hypolemic patient.

Several modalities can be used to evaluate occult cardiac injuries. In the hemodynamically unstable patient, the FAST can be carried out expeditiously. Echocardiography is sensitive in detecting pericardial fluid, and specific signs of tamponade can be demonstrated by echocardiogram before they become clinically evident, such as diastolic collapse of the atrium or ventricle. Cardiac ultrasound and echocardiography have been used with good reliability to evaluate penetrating intrapericardial injury.¹⁴⁰ Echocardiography was found to be 97% specific and 90% sensitive in stable patients with precordial wounds.¹⁴¹

All patients with penetrating thoracic trauma and echocardiograms or FAST scan pericardial views that demonstrate free pericardial fluid or that suggest clotted lacerations should be explored surgically. This is based on poor outcomes in patients who are initially managed nonoperatively. One study showed that two of three

patients in clinically stable condition and with ultrasound suggesting clotted laceration subsequently became unstable, and only one of these patients survived.¹⁴² Patients with echocardiographic evidence of even small amounts of pericardial effusion were found to have major intrapericardial injury at exploration.¹⁴³

CT scan is another noninvasive modality to evaluate cardiac injury, although it might also fail to pick up subtle injuries or small amounts of pericardial fluid. While not sensitive for small amounts of fluid, it is an excellent means of identifying and localizing intrapericardial or intracardiac foreign bodies, such as bullets and gunshot pellets. These foreign bodies should be removed in most circumstances to prevent embolization and infection. Because of a lack of sensitivity in imaging modalities, a high degree of clinical suspicion needs to be exercised when hemodynamic instability suggests cardiac injury despite a normal echocardiogram, and more invasive measures must be taken. All patients suffering penetrating trauma with sonographic evidence of intrapericardial fluid should undergo pericardiotomy, preferentially through a subxiphoid approach.¹⁴⁴ Minimally invasive evaluation has been recommended in select, stable patients using a subxiphoid pericardial window (Fig. 7-11).¹³⁹ Pericardial windows have also been performed using laparoscopic and VATS approaches.¹⁴⁵⁻¹⁴⁷ Upon performing pericardiotomy, if persistent hemorrhage is appreciated, formal exploration should use a median sternotomy to gain better exposure to the heart and great vessels.

Successful repair of penetrating cardiac trauma was first described in 1896 when Dr. Ludwig Rehn, a surgeon in Frankfurt, Germany, primarily repaired a stab wound to the right ventricle in a 22-year-old man in hemorrhagic shock with silk suture using a left thoracotomy incision.¹⁴⁸ Today, management of penetrating injuries to the heart follows standard principles of cardiac

surgery. If cardiac injury is suspected and time allows, transfer to the operating room with median sternotomy is performed. Otherwise, left anterolateral thoracotomy using a fourth interspace incision with extension across the sternum to the right chest if necessary is performed. Minimally invasive procedures are not advocated in the setting of hemodynamic compromise and suspected cardiac injury. Unilateral VATS or laparoscopy is an option in patients in stable condition in whom diagnosis is unclear. Management of ventricular stab wounds should be repaired using mattress sutures with large, full-thickness bites across the injury. A 2-0 large needle with Ethibond suture and Teflon pledgets is used to prevent tearing of the myocardium. Bleeding should be controlled using manual pressure or a sponge stick until sutures can be applied. In general, insufflation of a Foley balloon to tamponade a ventricular or atrial defect is not advocated, given the possible interference with the valvular apparatus of the tricuspid or mitral valve or obstruction of either the right or left ventricular outflow tract. Finally, the use of a Foley catheter increases the likelihood of pulmonary air embolus or stroke.

Repair of atrial injuries with 4-0 polypropylene suture is recommended. Pledgets can be used depending on the quality of the atrial tissue and size of the defect. Autologous pericardium can be used to reconstruct larger defects. Hemorrhage can be extraordinary, necessitating massive transfusion of blood products. An intraoperative cell salvage system should be used whenever possible should a perfusionist be available. Coronary injuries present a particularly challenging injury and carry a high mortality; this is due to blood loss, early tamponade, and the resultant myocardial ischemia that can produce hemodynamic instability secondary to myocardial failure. Mattress sutures beneath the coronary artery that control bleeding but do not completely obstruct coronary flow should be attempted whenever possible (Fig. 7-12).

Left main and anterior descending artery injuries likely produce the most catastrophic outcomes given the large territory of myocardium that the vessel supplies. Hemorrhage from coronary injuries can be temporarily controlled using a small gauze on the end of a hemostat to compress the artery both proximal and distal to the injury. Direct repair or off-pump coronary bypass is likely to be impractical but might be considered if a cardiac surgeon with the equipment and experience is available. Ligation or oversewing of a major coronary artery should be undertaken only as a last option. If the hemodynamic instability is encountered after ligation, institution of cardiopulmonary bypass and performance of coronary artery bypass grafting distal to the area of ligation should be considered.

Intrapericardial great vessel injuries are unusual because of their short segments, but they carry a high mortality. Intrapericardial aortic injuries were uniformly fatal in one series.¹⁴⁹ Lacerations to the intrapericardial aorta can be repaired using basic vascular technique, a side-biting vascular clamp, and oversewing with 3-0 prolene suture. Temporary inflow occlusion of the inferior vena cava (IVC) and superior vena cava (SVC) can be used to try to minimize hemorrhage while performing the repair. Gunshot injuries producing a significant aortic

FIGURE 7-11 ■ Subxiphoid approach for pericardial window. (From Brown J, Grover FL: Trauma to the heart. *Chest Surg Clin N Am* 7:325, 1997.)

FIGURE 7-12 ■ Suture repair of ventricular injuries positioned next to the coronary vessels. (From Blaisdel FW, Trunkey DD, editors: *Cervicothoracic trauma*, ed 2, New York, 1994, Thieme Medical Publishers.)

disruption are usually fatal; however, if cardiopulmonary bypass is available, aortic cross-clamping for repair and grafting is optimal.

SVC and IVC injuries are also difficult to control. Lifting or pulling on the heart to expose these injuries usually results in hemodynamic instability in the hypovolemic patient; therefore, volume loading is critical. Side-biting vascular clamps can be used to control smaller, tangential injuries, but they can result in iatrogenic injury if not placed with care on fragile tissue. Shunts such as chest tubes and endotracheal tubes have been recommended to control hemorrhage but can be cumbersome to use. Care must be taken not to worsen the original injury. Cardiopulmonary bypass can be used for SVC or IVC drainage; it allows more controlled repairs of complex injuries. Circumstances that might necessitate cardiopulmonary bypass include exsanguination uncontrolled by other measures, injury to a coronary artery, valvular injuries, intracardiac septal defects, and retained intracardiac foreign bodies.¹⁴⁸ Cardiopulmonary bypass, while uncommon for use in emergency penetrating injuries to the heart, has been used with success if applied in a timely manner.^{150,151} Outcomes for patients with penetrating wounds to the heart show that gunshot wounds have lower survival than stab wounds do. Multiple chamber injuries or penetrating injuries to intrapericardial great vessels were found to have a reduction in survival rate to nearly one fourth of survival rates for single-chamber injuries. Patients with lower physiologic status had lower survival than did those with higher physiologic status.¹⁴⁹

Air Embolism and Bullet Embolism

Bullets and other missiles are not routinely removed from the chest if associated injuries are excluded. Foreign body embolism to the heart is rare. It occurs when missiles migrate intravascularly from sites of more peripheral injuries. Diagnosis is made with chest radiography, CT

scan, echocardiography, or fluoroscopy. The management of intracardiac foreign bodies in asymptomatic patients has been debated, ranging from a philosophy of removing all intracardiac foreign bodies to expectant management. Most surgeons recommend selective management.

The presence of an intracardiac foreign body must first be determined to be embolic and not from direct thoracic injury. Direct injury resulting in an intracardiac foreign body clearly mandates sternotomy to evaluate a penetrating cardiac injury. However, if there is no thoracic injury, intracardiac missiles can be assumed to be embolic. Workup should include a chest CT scan and two-dimensional echocardiogram.¹⁵² CT scan helps to localize the foreign body. Echocardiography confirms its presence and determines the exact location of the embolus in relation to other cardiac structures and whether there is any valvular dysfunction or septal defect. In addition, echocardiography can determine whether the missile is fixed or whether it is mobile. Because of their embolic nature, these missiles are generally on the right side of the heart. If these right-sided missiles appear stable and without tumbling movement on echocardiography and appear lodged in a chamber or ventricular wall, they can be followed expectantly.^{153,154} Some authors recommend intervention on larger missiles (greater than 5 mm), irregularly shaped missiles, missiles proximal to an artery, and left-sided intracavitary or partially embedded missiles.¹⁵⁵

In general, intracardiac embolic missiles should be removed if they are left sided, mobile, large, or symptomatic with valvular incompetence. Anticoagulation or prophylactic antibiotics are not recommended for expectant management, but follow-up echocardiogram at 3 months, 6 months, and 1 year is recommended.

Systemic air embolus is a relatively uncommon but frequently unrecognized cause of death in patients with penetrating lung injury. This generally occurs in the setting of patients with a central lung injury. A missile or stab wound creates a fistula from the bronchus to the pulmonary veins, producing an air embolus in patients when placed on positive-pressure ventilation. This is believed to occur more often in the setting of high airway pressures. Cardiovascular collapse occurs when air enters the coronary arteries, causing myocardial ischemia resulting in ventricular fibrillation or asystole. The hallmark of an air embolus is hemoptysis and bloody, frothy air leak from a lung injury. This can then be confirmed intraoperatively by visualizing air in the coronaries.¹⁵⁶

If air embolus is suspected, immediate thoracotomy should be performed to the side of the injury. The hilum of the lung should be clamped to prevent further sources of embolus. The patient should be placed with his or her head down to prevent cerebral embolus. Removal of a massive air embolus can then be performed using a large-gauge needle and syringe through the left ventricular apex or through the roof of the left atrium as open cardiac massage is performed. Coronary air emboli can also be removed using a syringe and small gauge needle. Outcomes for massive air embolus are poor, with only 3 of 9 patients surviving in a small series by Estera and colleagues.¹⁵⁶ Prevention of this problem is paramount and should include lung isolation to prevent positive

pressure on an injured lung until repair or resection is performed.¹⁵⁷ Management has also been described using prompt institution of cardiopulmonary bypass to restore circulation while lung resection and cardiac de-airing are performed.¹⁵⁸

Great Vessels

More than 90% of patients with great vessel injuries have penetrating thoracic trauma.¹⁵⁹ The thoracic great vessels include the ascending aorta, aortic arch and descending aorta, the innominate artery and veins, the subclavian artery and veins, pulmonary artery, and pulmonary veins. Injuries to the great vessels are challenging to manage. Most patients die before reaching the hospital. Of those who reach the hospital, most require immediate thoracotomy in the ED.^{160,161} Workup for major thoracic vascular injuries is frequently limited given the instability of these patients and their need for immediate surgical intervention. However, plain chest radiography may reveal hemothorax, hemopneumothorax, or mediastinal hematoma.

Further workup in the patient in stable condition should include a FAST scan focusing specifically on the pericardial view and chest CT with intravenous contrast or aortography. This is particularly pertinent in patients with a transmediastinal gunshot wound.^{162,163} Given the improved sensitivity of the new generation of CT scanners and the increased speed with which a CT scan can be performed, CT angiograms are replacing angiography as the diagnostic modality for these injuries. In addition, CT scan allows the identification of other thoracic injuries. Angiography can still be useful as a diagnostic tool in centers without adequate CT scanners or dedicated trauma radiologists, as well as a therapeutic, interventional modality to address selective injuries.

The initial management of major vascular thoracic penetrating injuries is prompt thoracotomy and manual tamponade of the injury or control with a vascular clamp. Subclavian injuries can be difficult to tamponade because of their location behind the clavicle. Foley balloon insertion into a neck wound and application of traction to tamponade the bleeding has been recommended until more definitive control can be achieved.¹⁶⁴

Definitive management of thoracic vascular injuries follows the principles of vascular repair. Aortic injuries are frequently lethal. Rapid exposure of these injuries to establish control is critical, and the appropriate choice of incision cannot be overemphasized. Ascending aortic and aortic arch injuries are best approached through a median sternotomy. Manual pressure or control with side-biting vascular clamps can allow for a primary repair. Cross-clamping the ascending aorta is not possible without cardiopulmonary bypass, because cessation of perfusion to the brain is not tolerated in a normothermic patient. Repair of complex vascular injuries has been described using cardiopulmonary bypass and deep hypothermic circulatory arrest.¹⁶⁵ Descending thoracic aortic injuries should be approached through a left thoracotomy. The descending aorta can be cross-clamped to achieve proximal and distal control and to perform a primary repair or interposition graft.

Pulmonary artery or vein injuries are best approached through a posterolateral thoracotomy. Proximal control of the pulmonary artery should be achieved as a first step and can be achieved with a tourniquet placed and cinched down to decrease blood loss and to allow better visualization for vascular repair. Similar control can be achieved on the pulmonary veins. Primary repair should be attempted. Pneumonectomy should be avoided because of the aforementioned increase in morbidity and mortality associated with procedure.

Vena caval and innominate vein injuries are also repaired using standard vascular techniques. The intrapericardial SVC and IVC can be difficult to expose and repair. They can be approached through a right thoracotomy or median sternotomy. Ligation of the SVC or IVC without shunting is not compatible with survival. Innominate vein injuries are best repaired through a sternotomy. The innominate vein can be ligated if repair is not possible given the existence of adequate collateral venous drainage.

Subclavian injuries are the most frequently injured thoracic great vessel, particularly given their exposure and vulnerability with penetrating neck injury.¹⁶¹ Surgical exposure for control of bleeding makes these injuries challenging. Many approaches have been recommended for control of the subclavian vessels. This includes a clavicular incision, clavicular incision combined with sternotomy (Fig. 7-13), "trapdoor" or upper sternotomy combined with fourth interspace anterior thoracotomy (Fig. 7-14), or a high anterior thoracotomy using a second or third interspace incision (Fig. 7-15). Each of these techniques has its advantages, and the choice of incision should be based on the surgeon's familiarity with the approach and whether the vascular injury is left or right sided or more proximal or distal. Left-sided subclavian injuries can be difficult to control through a sternotomy. In general, these injuries can be repaired primarily or if necessary with an interposition graft of autologous vein or prosthetic graft.¹⁶⁶

Currently, the role of endovascular stent grafts for nonaortic great vessel injury is being addressed.⁹⁶ Successful stenting for nontraumatic carotid and subclavian arterial pathologies has been well reported, but the application to traumatic injuries less so. It has been estimated that well over one third of all nonaortic great vessel injury would be amenable to stent graft placement, but higher risks of endoleak associated with injuries proximal to arterial origins and multiple branch points with risk of occlusion and distal ischemia are several cited reasons for the lack of progress in this area. Limited case series to date have reported endovascular stenting to be safe and efficacious in selected cases, with up to a 95% success rate at excluding the traumatic lesion. Rates of early graft failure owing to stenosis or thrombosis as well as late failure owing to intimal hyperplasia have been observed in the range of 5% to 10%.⁹⁶

Diaphragmatic Injuries

Diaphragmatic injuries in penetrating trauma can be difficult to diagnose although once the diagnosis is made, their management is straightforward. Any penetrating

FIGURE 7-13 ■ Clavicular incision and median sternotomy for exposure and control of the proximal innominate and right subclavian artery. (From Ravitch MR, Steichen FM, Schlossberg L: *Atlas of general thoracic surgery*, Philadelphia, 1988, WB Saunders, p 147.)

injury at the nipple line or below should be considered to have the potential for both abdominal and thoracic injury and traversal of the diaphragm. The dilemma in management is how to diagnose the injury and to inspect both the chest and diaphragm for injury. Injuries to the diaphragm may be small, but repair is indicated because of the potential for associated abdominal injuries and the long-term sequelae of chronic diaphragmatic hernia with the potential for bowel incarceration. Non-invasive methods used to diagnose diaphragmatic injury are chest radiograph and chest CT scan. However, these methods can be unreliable for the diagnosis of diaphragmatic injury, with accuracy rates of only 50%.¹⁶⁷ Other more invasive methods for diagnosing penetrating diaphragmatic injury are diagnostic peritoneal lavage (DPL), but this can also miss diaphragmatic injury. Therefore, some have recommended exploratory laparotomy in patients with penetrating wounds inferior to the fourth intercostal space anteriorly, sixth interspace laterally, or eighth interspace posteriorly because of the contour and insertions of the diaphragm.¹⁶⁸ Laparos-

copy and VATS have been used to improve diagnostic sensitivity in evaluating the diaphragm without resorting to laparotomy. VATS has proved to be a safe and reliable method of evaluating the diaphragm and diagnosing and treating a variety of thoracic trauma. Current recommendations incorporate concepts from these series (Box 7-3).^{146,147,169}

Clearly, anyone with indication for thoracotomy or laparotomy should have the diaphragm inspected at the time of surgery. For patients without hard signs for surgery, VATS is a reasonable approach in the setting of an abnormal chest radiograph with an entry wound in the zone of insertion of the diaphragm and in the setting of a high velocity injury in the proximity of the diaphragm. Clearly, a high degree of suspicion is warranted for diaphragmatic injury. Because the procedure is fast and simple with minimal morbidity, VATS should be used liberally when diagnosis is uncertain. Repair of the diaphragm can be performed using VATS coupled with standard suturing techniques and a running or interrupted method of repair. The diaphragm can be repaired

FIGURE 7-14 ■ “Trapdoor” incision for exposure and control of the distal right subclavian artery injuries, which can be used for the left as well. (From Ravitch MR, Steichen FM, Schlossberg L: *Atlas of general thoracic surgery*, Philadelphia, 1988, WB Saunders, p 155.)

transabdominally should laparotomy be required. An interrupted repair (of polypropylene) rather than a continuous suture of the diaphragm should be used.

In one series of 171 patients with penetrating chest trauma, an algorithm was proposed to identify occult diaphragmatic injury. An initial chest radiograph was obtained, followed by chest tube placement should a pneumothorax or hemothorax be present. In addition, a DPL or abdominal CT was performed to assess abdominal injuries. Should the DPL or abdominal CT scan suggest abdominal injury or if the hemothorax was significant, the patient was taken to the operating room and the diaphragm was evaluated using laparotomy or thoracotomy. In patients in stable condition with findings that did not mandate thoracotomy or laparotomy, VATS inspection of the diaphragm was recommended when two or more of the following findings were present: abnormal chest radiograph, associated abdominal injury, high-velocity injury, injury inferior to the nipple, or a right-sided wound.¹⁷⁰

Esophageal Injuries

Injuries to the intrathoracic esophagus owing to penetrating injury are rare. The esophagus is more commonly injured in the neck, where it is most exposed; however, thoracic esophageal injuries carry a high morbidity and mortality. In a multicenter cross-sectional study, thoracic trauma with an associated esophageal injury was associated with a nearly threefold increase in the need for operative intervention and almost a twentyfold increase in mortality rate.¹⁷¹ The reasons are multiple. Given its central location in the chest, associated injuries are extremely common (98%) in one series.^{172,173} In addition, these injuries can be missed unless specifically investigated. Finally, repair of the esophagus can be technically difficult and associated with morbid complications. A multicenter study of penetrating esophageal injuries showed that preoperative workup of esophageal injuries resulted in delay in surgery and poorer outcomes.¹⁷⁴ They concluded that if selective evaluation and management of

FIGURE 7-15 ■ Clavicular incision for exposure and control of distal left subclavian artery injuries, and separate upper anterior thoracotomy for proximal control. (From Ravitch MR, Steichen FM, Schlossberg L: *Atlas of general thoracic surgery*, Philadelphia, 1988, WB Saunders, p 150.)

BOX 7-3 Role of Video-Assisted Thoracic Surgery in Thoracic Trauma

INDICATIONS

- Treatment for ongoing thoracic hemorrhage
- Treatment of retained hemothorax
- Treatment of persistent pneumothorax
- Diagnosis and treatment of diaphragmatic injuries
- Pericardial window for relief of cardiac tamponade
- Management of thoracic duct injuries
- Treatment of posttraumatic empyema
- Removal of foreign bodies

RELATIVE CONTRAINDICATIONS

- Coagulopathy
- Prior thoracotomy

ABSOLUTE CONTRAINDICATIONS

- Hemodynamic instability
- Suspected cardiac injury
- Suspected great vessel injury
- Inability to tolerate single lung ventilation
- Inability to tolerate lateral decubitus position

injuries is to be performed, it should be done rapidly with the plan of expeditious transfer to the operating room. If this is not possible, they recommend proceeding to prompt surgical exploration.

Investigation for esophageal injuries depends on the stability of the patient. If the patient's condition is stable with a mediastinal or transmediastinal gunshot wound, CT scan of the chest should be performed immediately

with intravenous contrast and injection of Gastrografin contrast through a nasogastric tube. This can help to delineate associated injuries and the course of the bullet and help to choose a surgical approach. If the patient's condition is not sufficiently stable to undergo CT scan and emergent operative exploration is necessary, then intraoperative flexible bronchoscopy and esophagoscopy should be performed first, followed by thoracotomy on the side in which major associated injury is suspected. Thoracotomy should be performed to the left side if the injury is uncertain, to have access to the descending aorta for cross-clamping should this prove necessary. Lung isolation through a double lumen endotracheal tube or bronchial blocker is preferable to provide atelectasis for better visualization and to optimize repair of injuries. Flexible endoscopy for the diagnosis of esophageal trauma has been shown to be an excellent diagnostic tool (100% sensitivity, 96% specificity with 97% accuracy in one study).¹⁷⁵ Intraoperative insufflation of air through the esophagoscope with the chest filled with saline can help to identify a small injury. More proximal injuries are best explored through the right chest through the fifth intercostal space, particularly if associated airway injury is suggested. Bronchoscopy is mandatory to examine both the trachea and the more distal airway for injury. Distal esophageal injuries around the esophagogastric junction are best explored through a sixth interspace left thoracotomy.

Thoracic esophageal injuries should be repaired using primary closure with wide drainage. Prompt recognition of esophageal injury is critical, and the injury must be repaired. Missed diagnosis allows mediastinal soilage

with ensuing sepsis in a patient who has already undergone one physiologic insult. Nonoperative chest tube drainage alone has no place in the management of penetrating esophageal injuries. One series had a 50% mortality in this setting.¹⁷⁶

The injured esophagus should be débrided back to clean, viable tissue. Like other esophageal repairs, a two-layer closure is done with attention to a watertight mucosal closure using absorbable suture with an overlying second layer of nonabsorbable suture to close the muscular layer. The repair should be covered with an intercostal muscle flap or the fundus of the stomach if the injury is close to the gastroesophageal junction. Multiple chest tubes should be used to ensure complete drainage of the hemithorax and complete reexpansion of the lung to seal the pleura against the closure. In addition to chest tubes, soft, closed suction drains (e.g., Jackson-Pratt or Blake drains) should be left close to the area of injury. Therefore, should the repair prove to leak postoperatively, the chest tubes can be removed slowly, and the patient can eventually be discharged from the hospital with the Jackson-Pratt drain in controlling the leak until it seals. Gastric and jejunal feeding tubes should be considered and placed operatively either at the time of initial surgery or at a second operation to provide access for long-term feeding should a postoperative leak preclude oral intake. Esophageal repairs are evaluated for leak with a barium esophagram on postoperative day 7.

COMPLICATIONS OF THORACIC TRAUMA

A complete discussion of complications following thoracic trauma is beyond the scope of this chapter, but the more common problems are listed in Box 7-4. Many complications and their therapies are similar to their counterparts found in nontrauma settings, and the reader is referred to those specific sections in this textbook; however, several issues specific to thoracic injuries are important to note.¹⁷⁷

Acute Lung Injury and Respiratory Distress Syndrome

Up to 20% of cases of acute respiratory distress syndrome (ARDS) in the United States are caused by thoracic trauma. Whether a direct injury to the lung parenchyma was incurred or was a sequela of the critically injured patient, mortality from ARDS remains approximately 50%. Differentiation from acute lung injury may be difficult, and it is sometimes included in the spectrum of diseases; both reflect the concept of acutely occurring nonhydrostatic pulmonary edema, infiltrates on chest radiography, and hypoxemia, which are generally worse in ARDS.¹⁷⁸ With alterations in immune competence and production of proinflammatory cytokines, the systemic inflammatory response can develop and can progress to septic shock and ARDS with a proven infection source.¹⁷⁹ Regardless of the etiology, the development of ARDS is difficult to predict, but there are several factors that increase the risk of ARDS in these patients (Box 7-5).

BOX 7-4 Complications of Thoracic Trauma

PULMONARY

- Atelectasis
- Acute respiratory distress syndrome
- Acute lung injury
- Pneumonia
- Infarction
- Lung abscess
- Arteriovenous fistula
- Bronchial stenosis
- Tracheoesophageal fistula

PLEURAL SPACE

- Empyema
- Bronchopleural fistula
- Organized hemothorax
- Chylothorax
- Fibrothorax
- Diaphragmatic hernias

VASCULAR

- Thromboembolism
- Air embolism
- Pseudoaneurysm
- Great vessel fistula

CHEST WALL

- Hernias
- Persistent pain

MEDIASTINUM

- Mediastinitis
- Pericarditis

BOX 7-5 Acute Respiratory Distress Syndrome Risk Factors

- Pneumonia with aspiration
- Pulmonary contusion with penetrating injury
- Closed head injuries
- Orthopedic injuries
- Sepsis or infections
- Multiple transfusions
- Pancreatitis
- Coagulopathies
- Inhalation injury
- Burns

Therapy for ALI and ARDS is mainly supportive and is directed at correcting the possible underlying etiology that precipitated the pulmonary problem.^{180,181} Other therapies include mechanical ventilatory support with or without oscillation, adequate nutritional status, minimization of fluid requirements, permissive hypercapnia to minimize barotrauma, and constant rotation of position to redistribute pulmonary edema. Pharmacologic therapy includes inhaled nitric oxide, exogenous or aerosolized surfactant, corticosteroids, and the use of mediator-directed therapy such as nonsteroidal anti-inflammatory drugs and monoclonal antibodies directed against endotoxin. In addition, extracorporeal membrane oxygenation

has been used to support these patients. Although most mediators have not shown vast improvement in a prospective fashion, these nonconventional therapies still hold great promise.

Pneumonia

Pneumonia remains the most common infectious complication after any polytrauma, particularly those involving the thorax. The incidence increases with the duration of endotracheal intubation, and it is associated with up to 50% of deaths following trauma. The etiology of nosocomially acquired pneumonias can be complex and related to a number of factors: underlying pulmonary conditions, associated injuries, multiple antibiotic therapies, colonization of the upper airway, aspiration at the time of initial injury, impairment of local defenses, and depression of the immune response.

Diagnosis is often difficult, with only half presenting classically with fever, leukocytosis, respiratory distress, and an abnormal chest radiograph. Sputum sampling is essential; however, in the intubated patient, invasive testing is required, such as transtracheal or bronchoscopic aspiration with bronchoalveolar lavage. Pleural effusions can occur and are seen in 50% of patients with *Haemophilus influenzae* pneumonia.

Broad-spectrum antibiotic therapy is used initially, but it is narrowed once the offending organism and antibiotic sensitivities return. Other principles in therapy include good pulmonary care and toilet, and the maintenance of nutritional function. Prophylaxis is paramount, to include effective infection control and prophylactic antibiotic and gastric bleeding measures.

Pleural Space Problems

The incidence of posttraumatic empyemas ranges from 2% to 6%, which rises to 26% of patients developing pleural space infections after chest tube insertion.¹⁸² The management of these empyemas is the same as that resulting from parapneumonic processes, with goals of controlling infection, evacuation of pus, obliteration of the pleural space, and restoring complete lung expansion. However, it is postulated that these empyemas differ from their parapneumonic counterparts in several aspects. Posttraumatic empyemas usually include, in addition to gram-positive organisms, a gram-negative component, which is a frequent consequence of retained hemothorax. In addition, these infections have an effusion that is often thick and of little volume, is not in the early or exudative phase, and requires open thoracotomy, drainage, and aggressive decortication.¹⁸³

Bronchopleural Fistula

Persistent bronchopleural fistula is a common problem following significant penetrating trauma to the lung parenchyma. Massive air leaks, identified with a loss of 30% to 50% of the tidal volume, are usually due to main-stem bronchial injuries, and they require immediate surgery. Fistula persisting more than 7 to 10 days is an indication for operative intervention. The use of

sclerosing agents has been reported, but failure rates are high. If surgery is performed in the persistent parenchymal fistula, careful dissection and closure is advised because of the friability and fragility of the tissues, sometime in the presence of ARDS inflammatory changes. The internal parenchymal injury should be exposed, and major bronchioles are oversewn. The parenchyma is closed in layers, and the visceral pleural lining is oversewn with a running suture to minimize air leaks. If the parenchyma is not properly closed in layers, a parenchymal cavity will persist and act as a nidus for a lung abscess. Anatomic resection is rarely needed; if it is required, wedge resection usually suffices.

Great Vessel Fistula

Nearly all traumatic arteriovenous fistulas result from penetrating injuries. Although a majority occur in the cervicomedial region, approximately 30% are found in the intrathoracic great vessels.¹⁸⁴ A thrill is heard in only 20% of patients 1 week following the injury, and increases to 100% at 2 weeks. At 12 weeks, 85% will have some type of significant clinical presentation.

Surgery is recommended once the fistula is demonstrated radiographically, usually by angiography. There is no role for fistula "maturation," as venous hypertension can cause bleeding complications during and after the repair. Autogenous vein patch is suggested for peripheral vessels, whereas prosthetic grafts are reserved for the great vessels, aorta, and main pulmonary artery. Endovascular stenting and embolization have been reported; however, selective use of these methods is suggested for smaller vessels.

SUMMARY

A variety of benign and malignant lesions can develop in the trachea and lead to airway obstruction. The infrequent occurrence of tracheal pathology and its frequently insidious nature can lead to a delayed diagnosis for patients in whom these conditions exist. Advances in surgical and anesthetic techniques have enabled safe and effective resection with primary reconstruction for many of these lesions. For obstructive lesions whose extent precludes primary tracheal resection and reconstruction, there is still no universally definitive treatment, but several palliative measures exist to provide patients with a satisfactory airway. Most recently, several reports of tracheal replacements using tissue-engineered grafts have generated hope for these patients.

This chapter focuses on surgically correctable lesions of the trachea, including those that involve the subglottic larynx. Pathology and treatment of carinal lesions will be discussed in a separate chapter. Historical perspective, along with preoperative assessment, operative strategies, and postoperative care for patients with obstructive pathology of the trachea will be discussed in detail.

HISTORICAL PERSPECTIVE

When the field of tracheal surgery was young, it was widely accepted that only four tracheal rings, or approximately 2 cm, of trachea could be resected safely with immediate reconstruction. It was the work of Dr. Hermes Grillo, widely considered the father of modern tracheal surgery, that led to the surgical practices used today.

Grillo et al¹⁻³ systematically investigated the limits of resection of the trachea to permit reconstruction without excessive anastomotic tension. Among other findings, these studies demonstrated that the tracheal blood supply entered in its lateral pedicles, and that safe mobilization of the trachea could be accomplished only with anterior and posterior dissection. Dedo and Fishman⁴ described laryngeal release maneuvers to minimize tension on lengthier tracheal resections. These contributions led to the realization that, in extreme cases, up to 50% of the human trachea could be resected and reconstructed without detrimental tension.

ANATOMY

The trachea averages 11 cm in length from the lower border of the cricoid cartilage to the carinal spur, with an additional 1.5 to 2 cm of subglottic laryngeal airway. The structural support comes from 18 to 22 cartilaginous C-shaped rings, with about two rings per centimeter. The cricoid cartilage is the only complete cartilaginous ring in the normal airway. Most of the trachea lies within the thoracic inlet and the chest. Cervical hyperextension delivers up to half of the trachea into the neck, and flexion devolves most of the trachea into the mediastinum.

The blood supply to the trachea is provided by many segmental end arteries. The upper trachea is supplied principally by branches of the inferior thyroid artery, and the lower trachea by branches of the bronchial arteries.

FIGURE 8-1 ■ Microscopic blood supply of the trachea. Transverse intercartilaginous arteries derived from the lateral longitudinal anastomosis penetrate the soft tissues between the cartilaginous rings to supply a rich vascular network beneath the endotracheal mucosa. (From Salassa JR, Pearson BW, Payne WS: Gross and microscopical blood supply of the trachea. *Ann Thorac Surg* 24:100–107, 1977. Reprinted with permission from the Society of Thoracic Surgeons.)

These vessels enter the trachea via very fine lateral pedicles and lack intersegmental collateralization (Fig. 8-1).⁵ The pretracheal plane and the plane between the esophagus and the trachea are avascular. The recurrent laryngeal nerves ascend in the tracheoesophageal grooves bilaterally and pass medially to the inferior cornua of the thyroid cartilage to enter the larynx. The nerve on the left is present along the entire length of the trachea, whereas the right recurrent laryngeal nerve is present in the tracheoesophageal groove for only the proximal cervical trachea.

TRACHEAL PATHOLOGY

A wide spectrum of pathology can afflict the trachea, ranging from benign conditions to malignant ones. Most conditions lead to central airway obstruction with subsequent respiratory insufficiency. Others, such as fistulas between the trachea and innominate artery or esophagus, can also occur and be equally deleterious. Direct external trauma, blunt or penetrating, can result in a tear or complete disruption of the trachea at any level. Inhalational burn injuries are usually maximal in the proximal subglottic region and diminish in the more distal airway. In most cases, the tracheal rings are not destroyed.⁶ Idiopathic laryngotracheal stenosis appears to be a distinct disease entity, which leads to an inflammatory process in the subglottic region. This is an unusual problem almost exclusively occurring in white women most commonly in the third to fifth decade of life.⁷

Postintubation Injuries

Iatrogenic injuries resulting from tracheal intubation have long been the most common lesion afflicting the airway. Postintubation injuries include granulomas, strictures, malacia, and tracheoesophageal and tracheoinnominate fistulas (Fig. 8-2).

Postintubation tracheal stenosis represents the most common iatrogenic injury of the trachea. It occurs after

intubation and develops principally at the level of the endotracheal tube (ETT) or tracheostomy tube cuffs. The radial pressure exerted from the cuff causes circumferential pressure necrosis, which results in cicatricial scarring stenosis (Fig. 8-3).^{8,9} The route of entry of the ventilatory tube does not affect the occurrence of cuff injury, only its level. These lesions are seen in patients who have had only oral endotracheal intubation and in those with previous tracheostomy. The development of the large-volume, low-pressure cuff for tracheostomy and ETTs for ventilation has greatly lowered the incidence of cuff-related stenoses. However, overinflation of these cuffs can still result in local airway damage and subsequent scar formation, and it contributes to the continued incidence of these lesions. Stenosis in the subglottic region can occur because of prolonged intubation with ETTs, after cricothyroidotomy, or after high placement of a tracheostomy where the neck of the tube erodes through the cricoid cartilage.¹⁰

Stomal stenosis results from the gradual enlargement of a tracheal stoma and its eventual healing by contraction. This pulls the sides of the defect together, distorting the tracheal lumen to a triangular configuration, with the base of the triangle located posteriorly and consisting of the uninjured membranous wall (Fig. 8-4). The large stoma can result from overzealous excision of anterior tracheal cartilage at the time of the initial tracheostomy, from erosive infection around the margins of the stoma, or, most commonly, from erosion resulting from leverage by equipment attached to the tracheostomy tube during ventilation. The stenotic process can extend into the subglottic larynx if the previous tracheostomy was placed inappropriately high in the trachea.

Prolonged endotracheal intubation combined with a nasogastric tube can lead to a tracheoesophageal fistula (Fig. 8-5). This fistula results from pressure necrosis generated by a ventilating cuff in the trachea and a nasogastric feeding tube in the esophagus. Consequently, these fistulas occur in the shared location between the membranous tracheal wall and the anterior wall of the esophagus. Anterior injuries of the trachea can lead to the

FIGURE 8-2 ■ Diagrams of principal postintubation tracheal lesions. **A**, Cuff stenosis from the cuff of an endotracheal tube. **B**, Cuff stenosis from the cuff of a tracheostomy tube, usually lower in the trachea than that from an endotracheal tube. Stoma stenosis also occurs at the site of the tracheostomy itself. Malacia can occur either at the level of the cuff or in the segment between the stoma and the cuff stenosis. **C**, Cuff stenosis at the site of a high tracheostomy stoma, which has eroded into the lower margin of the cricoid cartilage. In older patients, this can erode back further into the subglottic larynx, producing a laryngotracheal stenosis. **D**, Tracheoesophageal fistula (TEF) produced by pressure of the cuff against the membranous wall, often abetted by an indwelling, firm, nasogastric tube. **E**, One type of tracheoinnominate fistula (TIF) is the result of a high-pressure cuff erosion. The more common type, but also rare, is that seen with a low-placed tracheostomy stoma, which rests against the innominate artery itself. Not shown here are the lesions that occur in the larynx as the result of endotracheal tubes. (From Grillo HC: Surgical management of postintubation tracheal injuries. *J Thorac Cardiovasc Surg* 78:860, 1979.)

FIGURE 8-3 ■ Cuff-level stenosis. The stenosis here is circumferential, and the remaining lumen is round.

FIGURE 8-4 ■ Tracheostomy stomal site stenosis. The characteristic A-shaped lumen is evident and results from a primarily anterior and lateral cicatricial process.

development of a tracheoinnominate artery fistula. These most often result from direct erosion of the inner elbow of the tracheostomy tube in an inferiorly placed stoma, and they can arise either from a tracheostomy tube placed too low in the trachea or from an innominate artery lying high, near the sternal notch.

Idiopathic Laryngotracheal Stenosis

Rarely, a patient has stenosis of the airway without history of trauma, infection, inhalation injury, or airway intubation. Idiopathic laryngotracheal stenosis is a diagnosis of exclusion, characterized by an inflammatory cicatricial

FIGURE 8-5 ■ Endoscopic view of a tracheoesophageal fistula.

stenosis at the level of the subglottic larynx, cricoid, and upper trachea.⁷ Causes such as gastroesophageal reflux with silent aspiration, Wegener granulomatosis, and connective tissue disorders must be excluded. As part of the routine preoperative workup, all patients undergo serologic screening (antinuclear antibody [ANA], antineutrophil cytoplasmic antibody [ANCA]) for these conditions. Over 95% of patients with idiopathic laryngotracheal stenosis are female between the third and fifth decade of life, and they typically exhibit signs and symptoms of upper airway obstruction. Pharyngeal and laryngeal anatomy and vocal cord function are usually normal, whereas the inflammatory process leading to luminal narrowing is confined intrinsically to the wall of the airway and the immediately surrounding connective tissue of a short (<2.5 cm) segment at the level of the cricoid cartilage.

The biggest clinical challenge in the surgical management of idiopathic laryngotracheal stenosis lies in the unpredictability and variability of the future clinical course. When airway obstruction becomes severe and dilation does not provide sustained relief of symptoms, surgery may be entertained, with, however, the clear caveat that the disease may progress. Most patients are best treated with definitive laryngotracheal resection and primary reconstruction.^{11,12} Timing of resection and reconstruction is central and must be done when inflammation is minimal. Bridging the time to definitive operation may require repeated bronchoscopic dilation. We prefer dilation to be performed in the operating room with rigid bronchoscopes starting with pediatric sizes increasing to adult bronchoscopes.

Tracheobronchomalacia

Airway malacia may be a consequence of a postintubation injury; however, in patients with chronic obstructive pulmonary disease, malacia can develop in the lower trachea, main bronchi, and sometimes the more distal bronchi, even in the absence of prior intubation.¹³ When the patient attempts a deep expiration or a cough, the mem-

branous wall approximates to the anterior, softened cartilaginous wall, causing nearly total obstruction. Subsequently, the posterior membranous wall elongates and becomes redundant. Afflicted patients may have dyspnea, cough, and secretion retention. It is possible to address the deformity surgically by pulling the ends of the cartilages toward one another posteriorly, restoring a more circular shape to the airway. The redundant membranous wall must be tacked to a posterior splinting material to prevent it from falling forward into the lumen. Various materials have been used for splinting, but none with complete success. These have included fascia lata, pericardium, lyophilized bone, polytetrafluoroethylene, and rigid plastic splints. Biomesh and cryopreserved aortic allografts can be useful biologic alternatives to synthetic tissues, especially when tissue quality or comorbidities are a factor, and airway erosion is of concern. To obtain maximum long-term relief, we currently use sheets of nonabsorbable polypropylene mesh to plicate the membranous wall as described by Rainer and colleagues.¹⁴

Tracheal Tumors

Primary tracheal tumors are rare, with an estimated incidence of 2.7 cases per million people per year.¹⁵ Approximately two thirds of primary tracheal tumors are either squamous cell carcinomas (SCCs) or adenoid cystic carcinomas (ACCs). These two types occur with equal frequency. The remaining third of the tumors are widely distributed in a heterogeneous group of tumors, both malignant and benign. Secondary tumors that involve the trachea include carcinomas of the larynx, thyroid, lung, and esophagus. Rarely, tumors metastasize to the submucosa of the trachea or to the mediastinum, with secondary invasion of the trachea.

Squamous cell carcinomas can be either exophytic (Fig. 8-6) or ulcerative. The tumor can metastasize to the regional lymph nodes, and, in its more aggressive and late forms, it invades mediastinal structures. In general, its progress appears to be relatively rapid in comparison with that of adenoid cystic carcinoma. A number of affected patients develop synchronous or metachronous second SCC primary cancers of the lung or oropharynx. Squamous cell carcinoma occurs predominantly in men who are cigarette smokers.¹⁶

ACC often has a prolonged course of clinical symptoms, sometimes extending for years. After resection, many years can pass before a recurrence is noted. ACC can extend submucosally over long distances in the airways and along perineural tissue. It can spread to regional lymph nodes, although this is less characteristic than in SCC. Although it can invade the thyroid or the muscular coats of the esophagus by contiguity, ACC that has not been surgically interfered with frequently displaces mediastinal structures before actually invading them. Metastases to the lungs, bone, and other organs can occur. These metastases can grow slowly over a period of many years and remain asymptomatic until they become large. In contrast to patients with tracheal SCC, the male-to-female ratio of patients with ACC is essentially equal, and any smoking history of these patients appears to be incidental.¹⁶

FIGURE 8-6 ■ An exophytic squamous cell carcinoma of the trachea.

FIGURE 8-7 ■ Bronchoscopic view of a papillary thyroid carcinoma with tracheal invasion.

The third group of primary tracheal tumors is composed of a multitude of tumor types and varying degrees of malignancy, including both epithelial and mesenchymal neoplasms. The list includes pleomorphic adenomas, leiomyomas, chondromas, carcinoid tumors, mucoepidermoid tumors, and sarcomas.

Secondary neoplasms can involve the trachea through direct extension. Thyroid carcinomas typically invade the trachea at the second and third rings, where the thyroid isthmus is adherent to the trachea (Fig. 8-7).¹⁷ More commonly, invasion is seen after thyroidectomy for carcinoma, when the surgeon was aware of shaving off the tumor from the trachea. In such cases, concurrent or early resection of the involved trachea should be considered. Both bronchogenic and esophageal carcinomas can erode into the trachea from local extension.

CLINICAL PRESENTATION

Patients with pathologic lesions of the trachea usually exhibit signs and symptoms of upper airway obstruction: dyspnea on exertion, wheezing, or stridor. Unfortunately, this presentation is frequently misinterpreted as adult-onset asthma, and it is not uncommon for patients to undergo treatment with corticosteroids for months to years before the correct diagnosis is finally made. Any patient with obstructive airway and a history of tracheal intubation must be considered to have airway stenosis until proven otherwise.

Tumors of the trachea often present insidiously. Their most common signs and symptoms are cough (37%), hemoptysis (41%), and the signs of progressive airway obstruction, including shortness of breath on exertion

(54%), wheezing and stridor (35%) and, less commonly, dysphagia or hoarseness (7%).¹⁵ Signs and symptoms can vary with the histology of the tumor. Hemoptysis is prominent in patients with SCC, usually leading to a prompt diagnosis. Patients with ACC more commonly exhibit wheezing or stridor as the predominant symptom, which often leads to a delay in diagnosis. In one study, the mean duration of symptoms before diagnosis in patients with SCC of the trachea was only 4 months, whereas in those with ACC it was 18 months.¹⁸

A tracheoesophageal fistula frequently appears as an increase in tracheal secretions and the appearance of orally ingested material in the airway. If the patient is using a mechanical ventilator, gastric distention can develop. Tracheoinnominate arterial fistulas may be heralded by a premonitory hemorrhage. In evaluating a patient with bleeding from a tracheostomy tube, it is important to determine whether the source is from erosion of tracheal granulation tissue or mucosal trauma, as opposed to the more deleterious arterial fistula.

RADIOGRAPHIC IMAGING

A standard posteroanterior chest radiograph, centered high on the trachea, may reveal some tracheal pathology. Detailed information about the location of the lesion, its longitudinal extent, and the amount of normal trachea available for reconstruction can be demonstrated by computerized axial tomography scans. These are particularly useful in evaluating tracheal tumors, as they characterize extraluminal extension and any mediastinal lymphadenopathy. Recently, the use of high-speed helical computed tomographic scanners to acquire images, combined

FIGURE 8-8 ■ **A**, Reformatted computed tomographic (CT) two-dimensional (2D) image of post-tracheostomy stenosis. **B**, A 2D image of an adenoid cystic carcinoma of the carina. **C**, Three-dimensional (3D) image of a tracheal airway column showing the endobronchial component of the same carinal mass. **D**, The same carinal mass as viewed endobronchially by a 3D image via virtual CT bronchoscopy.

with powerful three-dimensional-image software, has created impressive two- and three-dimensional airway reconstructions (Fig. 8-8).

BRONCHOSCOPY

Bronchoscopic evaluation is necessary to confirm a diagnosis, design an operative strategy, and ameliorate impending airway obstruction. Measurements taken with a rigid bronchoscope determine the amount of normal trachea that is available, both proximal and distal to the pathology, for reconstruction. Factors such as age, body habitus, prior surgery, and lesion location influence the amount of trachea that can be safely resected. With benign strictures, special attention must be given to evaluating the condition of the tracheal mucosa. Indwelling tracheostomy or tracheal T-tubes must be removed and

the mucosa assessed. If extensive mucosal inflammation or ulceration exists, definitive repair should be delayed until mucosal healing occurs. This may require a short period of decannulation or a change to a smaller T-tube. Often, patients with idiopathic laryngotracheal stenosis have active inflammation extending into the immediate subglottis. These patients should undergo dilation of their stenosis, and the operation should be delayed until the inflammatory state of the airway mucosa subsides. Patients taking corticosteroids should be weaned from them completely at least 1 month before an operative repair is undertaken. This is done to minimize the adverse wound-healing effects of these medications.

Expertise with the techniques of interventional bronchoscopy is essential to dilate a benign stenosis safely or “core out” an obstructing airway tumor. Coring out the tumor allows evaluation of the distal airway, safe passage of an ETT, or temporary creation of a patent airway to

allow delay in operation. Dilating a narrow, fibrotic stricture is challenging and can result in airway rupture, complete obstruction, or excessive destruction of tracheal mucosa. Progressively larger Jackson dilators passed through a rigid bronchoscope can be used to dilate the stenosis. An assortment of pediatric and adult rigid bronchoscopes can then be used, increasing the sizes and using a gentle corkscrew motion.¹⁹ Balloon dilators placed through the working channel of a flexible bronchoscope permit effective airway dilation, but we prefer rigid bronchoscopic dilation because of better control and visualization.

Obstructing tracheal tumors are managed first by core-out techniques using the rigid bronchoscope, forceps, and suction.²⁰ Using the tip of the bronchoscope in a corkscrew motion, most tumors can be débrided from the tracheal wall, and a forceps can then be used to remove dislodged tumor fragments. If bleeding ensues, the bronchoscope is advanced distal to the lesion and is used to tamponade the bleeding. Direct application of epinephrine-soaked pledgets can assist in achieving hemostasis.

Patients with critical airway stenosis should be assessed in the operating room where rigid bronchoscopy, biopsy forceps, and instruments required to perform emergent tracheotomy are available. Placement of a tracheostomy tube may be necessary in some patients as the only means to secure an airway. When possible, these tubes should be placed through the stenosis, preserving the uninvolved trachea for future reconstruction.¹⁹

ANESTHESIA

Anesthesia for airway surgery is challenging for both surgeon and anesthesiologist because of the underlying compromised airway and the necessity to share the airway during resection and reconstruction while maintaining respiration.²¹ Continuous close communication between the surgical and anesthesia teams is required throughout the case, particularly during the open airway phase of the operation. Clinical examination and history during preoperative evaluation, with special attention to exertion dyspnea and dyspnea at rest, the pattern of dyspnea, and the patient's ability to breathe comfortably in supine position, help to plan induction and airway management. In preparation for induction, an assortment of small-diameter ETTs (from 4.0 to 6.5), a sterile, spiral steel-enforced ETT (for ventilation across the surgical field), and a pediatric bronchoscope (in case the ETT needs to be checked, or in case of inadvertent extubation) should be immediately available. One or two midsize peripheral intravenous catheters and placement of an arterial line should be considered, whereas placement of a central venous line is usually not necessary. In patients with compromised airway, especially when there is a high degree of airway obstruction, usual intravenous induction is an acceptable choice (e.g., propofol, 2 mg/kg; fentanyl, 2 µg/kg; and cisatracurium, 0.15 mg/kg) to provide satisfactory anesthesia and muscle relaxation for rigid bronchoscopy and intubation. In selected cases, slow inhalative patient induction maintaining spontaneous ventilation

may be a valid alternative if there is a high degree of airway obstruction.²² This method can be safer than the administration of muscle relaxants, which paralyze respiration with a consequently urgent need to establish an airway.

The surgeon should have available an array of rigid bronchoscopes from pediatric to adult sizes as the induction commences. The residual airway through which the patient is breathing may be as narrow as 2 or 3 mm in diameter. In most cases, tumors are not circumferential. After bronchoscopy, a small ETT can often be insinuated past a highly obstructive lesion. Although not ideal, an ETT can be secured above the obstructive pathology.

At the time of tracheal division, the ETT is pulled back under direct vision, after a flexible red rubber catheter has been sutured to the Murphy eye of the ETT. The red rubber catheter serves as a guide for blind re-advancement of the ETT during the later phase of reconstruction. To maintain ventilation, a sterile, cuffed, and armored ETT is inserted into the distal airway across the operative field. Sterile connecting tubing is passed to the anesthesiologist to allow ventilation of the patient. This armored tube is removed whenever necessary for suctioning or placement of sutures. Toward the completion of the operation, the original ETT is advanced into the distal airway and the anastomotic sutures are tied. High-frequency ventilation has been used with equal success intraoperatively, but we have been quite satisfied with the technique described here. High-frequency ventilation is especially useful in certain complex carinal reconstructions.

Anesthesia is maintained with total intravenous anesthesia using short-acting agents such as propofol and agents blunting airway reflexes such as remifentanyl. This allows for quick emergence and immediate extubation at the completion of the procedure and maintains continuous anesthesia during periods when inhalational agents are interrupted by the procedure. Both teams have to be at the bedside during emergence and extubation, because most severe complications such as anastomotic disruption can occur during this critical stage of the operation. Tools for airway rescue such as laryngoscopes, bronchoscopes, ETTs, and laryngeal mask airways have to be immediately available. In general, the patient should be extubated and be able to breathe spontaneously at the conclusion of the procedure. Particularly when the trachea has been greatly shortened, it is desirable not to have even a low-pressure cuff lying in contact with the anastomosis. To optimize the immediate postoperative period, we routinely use techniques to keep the upper airway clear, including good oropharyngeal suctioning, antiemetics, and elevation of the head of bed. If swelling is anticipated, nebulized epinephrine can be a useful tool, while we try to avoid corticosteroids in the immediate postoperative setting. To prevent disruption caused by inadvertent movements during emergence, after extubation, and during patient transfer, one member of the team should be designated to ensure that the patient's neck remains flexed at all times. The use of cardiopulmonary bypass is rarely necessary in adult tracheal surgery, but it may be required in some complex carinal reconstructions²³; however, it may be requisite in repairing congenital airway lesions in the

FIGURE 8-9 ■ Resection of a midtracheal airway stenosis. See text for description of **A** to **D**. (From Grillo HC: Surgery of the trachea: current problems in surgery. *Ann Thorac Surg* 7:3–59, 1970. Reprinted with permission from Mosby, Inc.)

pediatric population, especially in the presence and correction of cardiac anomalies.²⁴

TRACHEAL RESECTION

For uncomplicated resections of the middle and upper trachea, the patient is positioned supine with neck extended using an inflatable airbag beneath the shoulders. The inflatable bag facilitates exposure by extending the neck during dissection, and when deflated, it allows cervical flexion just before the anastomotic sutures are tied. The head is supported in a foam ring, and the arms are tucked at the sides. Care must be taken not to over-extend the neck to avoid compression injury of cervical nerve roots. In patients with limited cervical mobility, testing the range of motion and the limits of comfortable extension before induction can be highly informative.

A low collar cervical incision is adequate for most tracheal resections that involve the upper trachea. When the lesion involves the middle to lower trachea, vertical

extension with a partial sternal split facilitates exposure (**Fig. 8-9A**). Dissection is carried through the platysma, and subplatysmal flaps are elevated superiorly to the level of the thyroid cartilage and inferiorly to the level of the sternal notch. The strap muscles are separated in the midline, and a plane of dissection is established very close to the tracheal wall to avoid injury to the recurrent laryngeal nerves (see **Fig. 8-9B**). The pretracheal plane is dissected to the level of the carina. The investing fascia of the innominate artery and the adjacent mediastinal fat are left intact to guard against postoperative tracheoinnominate fistulization. Retraction on the innominate artery is kept to a minimum to avoid impeding cerebral blood flow. Compression can be monitored by a right radial arterial line.

The area of involved trachea is transilluminated with a flexible bronchoscope through the oral ETT, allowing the assistant to mark the distal extent of resection. The balloon of the ETT is deflated. The trachea is sharply dissected circumferentially at the most distal aspect of the lesion, with the dissection plane maintained on the

tracheal wall. The oral ETT is withdrawn into the upper trachea and sutured to a red rubber catheter as described earlier. The trachea is partially divided at the most distal extent of the lesion, and bilateral 2-0 Vicryl traction sutures are placed. These sutures are placed in the midlateral aspect of the tracheal wall 1 cm below the anticipated level of transection. Distal tracheal division is completed, and circumferential dissection of the residual distal trachea is limited to 1 cm to protect the segmental tracheal blood supply. A cuffed, wire-wound ETT is promptly passed into the distal tracheal segment and attached to sterile connecting tubing, and cross-table ventilation is instituted (see Fig. 8-9C). The diseased segment of trachea is sharply dissected from the esophagus and amputated at the most proximal extent of the lesion. Proximal 2-0 Vicryl traction sutures are then placed.

The patient's neck is then flexed and the anastomosis tested for tension by crossing the traction sutures. If the limits of flexion and safe dissection have been reached and anastomotic tension exists, then one can proceed with release procedures. When the surgeon is satisfied that the anastomosis will not be under tension, interrupted, 4-0 Vicryl anastomotic sutures are placed so that the knots will be on the outside, beginning posteriorly in the midline and proceeding around either side to the front (see Fig. 8-9D). The sutures are placed 5 to 6 mm from the cut edge of the trachea and 4 mm apart. They should encircle a tracheal ring on either side of the anastomosis to help prevent dehiscence. Frequently, the cross-field ETT must be withdrawn for short periods to allow accurate placement of the more difficult sutures or for suctioning blood from the distal airway. After placing the anterior sutures, the cross-field ETT is removed from the distal tracheal segment, and the oral ETT is advanced carefully beyond the anastomosis.

Before tying down the anastomotic sutures, the inflatable airbag beneath the shoulders is deflated, the 2-0 traction sutures are tied, and any last few degrees of neck flexion that may be required are instituted. The anastomotic sutures are then tied from anterior to posterior—the reverse order to that in which they were placed. After all knots are tied, we test patency of the airway by deflating the cuff and pressurizing the airway with 20 to 40 cm H₂O to listen for an air leak around the tube. The integrity of the suture line is tested under saline immersion with the cuff deflated. We inflate to 20, 30, and 40 cm H₂O. During this maneuver, it is necessary to occlude mouth and nose manually. The bilateral sternohyoid muscles are mobilized from their surrounding attachments and sutured to the anterior trachea, above and below the anastomosis, to serve as a vascularized tissue buttress. A closed suction drain is left in the pretracheal space.

A chin-to-chest suture is placed with the neck in moderate flexion to prevent cervical hyperextension. This suture is tied without slack to prevent neck extension for the first 5 to 7 postoperative days. Patients are extubated in the operating room. When postoperative intubation is thought to be necessary, a small ETT is left in place, and a stitch is placed at least two rings below the anastomosis to mark the site for possible future tracheostomy. This allows limited dissection and accurate placement in a

reoperative field. It is best to wait a few days before placing a tracheostomy to allow skin flaps and other tissue layers to seal before exposing them to airway secretions. This also allows postsurgical airway edema to resolve, possibly obviating the need for a tracheostomy. Extubation should be attempted in the operating room, where bronchoscopic evaluation and placement of a small tracheostomy tube can be performed if necessary. Careful positioning and fixation of sternothyroid and sternohyoid muscle flaps during the initial operation help to keep a possible tracheostomy separate from the resection wound bed. For tracheal tumors, the approach is slightly modified. Considerable experience is required to judge whether a tumor can be safely resected with sufficient tissue to provide a clear margin and yet allow successful primary reconstruction of the airway. This decision can be particularly difficult in patients with adenoid cystic carcinoma, because frozen sections may show microscopic tumor at grossly clear resection margins. The plane of tissue dissection in tumor cases must be kept away from the involved portion of trachea to ensure an adequate radial margin. By dissecting further away from the trachea, it endangers the recurrent laryngeal nerves more than during resections for benign disease. If one recurrent laryngeal nerve is involved by tumor, the nerve should be sacrificed. Adjacent paratracheal lymph nodes are resected en bloc with the specimen, but, to minimize devascularization of the airway involved in the tracheal anastomosis, extensive lymph node dissection should not be performed. Postoperative radiation therapy is often recommended in cases of bronchogenic or adenoid cystic carcinoma, unless it is contraindicated by performance status or anastomotic complications.¹⁵

The transthoracic approach, using a posterolateral thoracotomy through the fourth intercostal space, is used for tumors of the lower trachea and carina and for a few inflammatory lesions. An extra-long, single-lumen ETT with sufficient diameter is used to intubate the left main-stem bronchus for selective ventilation.

Dissection of the thoracic trachea is performed in a fashion similar to that for more proximal pathology. In cases of malignancy, effort is made to resect surrounding tissues with the tumor. Eventually, the trachea is dissected circumferentially below the tumor, and sometimes above it, although the upper portion of the dissection may be completed after division of the trachea below. Traction sutures are placed in the midlateral tracheal wall distal to the tumor. If the transection is close to the carina, the sutures are placed in the lateral walls of the right and left main bronchi. Again, anesthesia tubing brought across the field is joined to a flexible armored tube placed in the distal trachea or, preferably, the left main bronchus, to allow collapse of the right lung for better exposure while performing the anastomosis. If this results in significant intrapulmonary shunting, the right pulmonary artery may be gently clamped.

Flexion of the neck, even with the patient in the lateral thoracotomy position, delivers the proximal trachea into the thorax. Dissection anterior to the trachea and both main bronchi will provide additional mobility. These are important maneuvers for obtaining a tension-free anastomosis. In the resection of a malignant tracheal

tumor, paratracheal and subcarinal lymph nodes that are not in proximity to the mass should not be radically resected for fear of devascularization of the airway. The technique of anastomosis is similar for that used in the upper trachea.

LARYNGOTRACHEAL RESECTION

When an upper tracheal lesion involves the cricoid cartilage, a laryngotracheal resection will be necessary (Fig. 8-10). The operative procedure must be tailored to address the particular anatomic involvement encountered. The recurrent laryngeal nerves are protected by beveling off the cricoid anteriorly and laterally while preserving the posterior cricoid plate.^{25,26} The extent of anterior cricoid resection ranges from complete, with a line of transection through the cricothyroid membrane, to

none at all, depending on the extent of involvement. In patients with significant subglottic side-to-side narrowing, tailored partial resection of the lateral cricoid cartilage with subsequent resurfacing provides a technique to achieve a larger ventricle.²⁷ Tracheal resection depends on the distal extent of the lesion (Fig. 8-11A and B). The trachea is appropriately tailored so that the proximal trachea approximates well with the cut edge of the larynx (see Fig. 8-11C and D). Vicryl traction sutures are placed in the mid-lateral position both proximally and distally. Interrupted 4-0 Vicryl sutures are used to fashion the anastomosis. The traction sutures are crossed and tied, followed by the individual 4-0 Vicryl anastomotic sutures (see Fig. 8-11E and F).

When the lesion involves the posterior subglottic larynx, a line of mucosal division is performed high on the posterior cricoid plate to excise involved mucosa and submucosa. The posterior cartilage is not resected. Mucosal resection should not extend proximally beyond the superior border of the cricoid plate. A posterior broad-based flap of membranous wall is created and advanced to resurface the posterior cricoid plate (Fig. 8-12). Four to five sutures are placed through the cartilaginous portion of the inferior margin of the cricoid plate and the outer portion of the membranous wall of the trachea below the proximal edge of the flap in order to fix the membranous wall to the inferior edge of the cricoid plate.^{25,26} These base of flap sutures are vertical mattress sutures to allow the knots to be tied on the outside of the airway. The posterior portion of the anastomosis is made with interrupted 5-0 Vicryl sutures placed only through the full thickness of mucosa and submucosa of the posterior wall of the larynx, and then through the full thickness of the membranous wall of the trachea. For ease of tying, the knots can be on the inside of the anastomosis.

FIGURE 8-10 ■ Upper airway stenosis. **A**, High tracheal stenosis, easily treated by segmental resection and tracheotracheal anastomosis. **B**, Stenosis that reaches to the lower border of the cricoid cartilage. **C**, Stenosis of the lower subglottic larynx and upper trachea. The extent of the lesion anteriorly is so great that correction requires removal of the anterior portion of the cricoid cartilage. **D**, Stenosis that reaches to the glottis. There is no subglottic space to which an effective anastomosis can be made. Reprinted with permission from the Society of Thoracic Surgeons.)

RELEASE PROCEDURES

Dissection of the pretracheal plane combined with cervical flexion produces sufficient airway mobility to allow tracheal resection and primary reconstruction in most patients. When extensive resections are performed, further mobilization with certain maneuvers may be required to enable a tension-free anastomosis. This has been shown to be necessary in 8.3% of patients undergoing resections for postintubation stenoses and in 15% of patients undergoing resections for tumors.¹⁹ The location of the lesion is an important factor in determining which procedures will be of benefit.

Certain release maneuvers are more effective for achieving additional mobility of the cervical trachea, whereas others are more effective for freeing the intrathoracic trachea. When an upper trachea resection is performed, an additional 1.5 cm of length may be gained by releasing the larynx with a Montgomery suprahyoid release.²⁸ This is accomplished by dividing the muscles that insert on the superior aspect of the central part of the hyoid bone. The hyoid itself is then divided just lateral to its lesser cornua on both sides, and the stylohyoid tendons are divided (Fig. 8-13). Laryngeal release

maneuvers may predispose patients to postoperative aspiration, but in time this problem resolves in most patients.

For transthoracic tracheal resections, additional length is best achieved by hilar release.²⁹ Mobilization of the right hilum should be approached first, along with division of the inferior pulmonary ligament. A U-shaped incision is then made in the pericardium below the inferior pulmonary vein. The pericardium can be incised 360 degrees around the hilum for additional mobility. In this event, the vascular and lymphatic pedicle to the main-stem bronchus is left preserved behind the pericardium. If further mobility is needed, the left hilum may be similarly mobilized (Fig. 8-14); this can be accomplished through a median sternotomy by opening the pericardium, by bilateral thoracotomies or an extended clamshell incision. As with most airway surgery, neck flexion is helpful; however, laryngeal release has not been shown to produce meaningful mobility at the level of the carina.³⁰

REPAIR OF TRACHEOINNOMINATE AND TRACHEOESOPHAGEAL FISTULAS

Tracheoinnominate fistulas appear as either massive airway bleeding or episodic hemoptysis. Significant bleeding from around or through a tracheostomy should be evaluated in the controlled environment of the operating room. The surgeon should be prepared to manage massive airway bleeding before removing the tracheostomy cannula. The patient is then decannulated and a bronchoscopy performed. In the event of massive hemorrhage, control can usually be obtained by finger compression through the stoma, pushing anteriorly against the sternum at the site of bleeding. A small oral ETT is advanced into the airway beyond the finger and the cuff firmly inflated to ventilate and protect the lungs from aspiration of blood. If the fistula lies beyond reach, hemorrhage can be controlled by placing an inflated ETT cuff over the bleeding vessel.

Exposure is obtained through a collar incision at the level of the stoma, along with a vertical extension for sternotomy. With finger compression maintaining hemostasis, the vessel is dissected to obtain proximal and distal vascular control. The involved segment of artery is resected, and the proximal and distal ends are oversewn. The stumps are covered with surrounding, well-vascularized tissue. Innominate division usually does not result in neurologic sequelae. Depending on the degree of airway destruction, a concomitant tracheal resection may be necessary. A new tracheal stoma is created at a higher level, and a tracheostomy tube long enough to pass beyond the previous stoma is used. Local strap muscle flaps are sutured over the original stoma to hasten its healing. In contaminated fields, transfer of omentum can be a useful backup source of well-vascularized tissue that can be mobilized with a midline extension of a median sternotomy incision.

Acquired, nonmalignant tracheoesophageal fistulas often appear while the patient remains ventilator-dependent. The fistula develops at the level of the cuff and is usually associated with a circumferential tracheal injury.³¹ Temporizing measures are taken to allow weaning from the ventilator before repair is undertaken. A tracheostomy tube should be positioned with the occluding cuff located below the fistula to prevent contamination of the tracheobronchial tree. Gastrostomy and jejunostomy tubes should be placed for drainage and feeding, respectively. The esophagus is kept free of tubes, and cuff overinflation is assiduously avoided. Before successful surgical repair can be attempted, pulmonary sepsis has to be controlled with adequate, tailored antibiotic coverage and aggressive pulmonary toilet. Ideally, the patient should be weaned or ready to be weaned from ventilator support before undergoing surgery, to minimize the need for mechanical ventilation, and prolonged intubation in the immediate postoperative period.

A collar incision is performed that encompasses the stoma (Fig. 8-15). As described previously, the trachea is dissected and divided distal to the fistula. As the posterior

FIGURE 8-15 ■ Exposure for most tracheoesophageal fistulas is through a low collar incision. Occasionally, a partial upper sternotomy is required for more distal exposure of the trachea. (From Mathisen DJ, Grillo HC, Wain JC, et al: Management of acquired nonmalignant tracheoesophageal fistula. *Ann Thorac Surg* 52:759–765, 1991. Reprinted with permission from the Society of Thoracic Surgeons.)

FIGURE 8-16 ■ Circumferential dissection above and below the fistula is performed in close proximity to the trachea to avoid injury to the recurrent laryngeal nerve. Division of the damaged trachea gives excellent exposure of the esophageal defect. (From Mathisen DJ, Grillo HC, Wain JC, et al: Management of acquired nonmalignant tracheoesophageal fistula. *Ann Thorac Surg* 52:759–765, 1991. Reprinted with permission from the Society of Thoracic Surgeons.)

wall of the trachea is dissected from inferior to superior, the fistulous connection is isolated circumferentially and detached from the esophagus with a small rim of normal esophageal tissue (Fig. 8-16). After removal of the specimen, the esophagus is closed longitudinally with two layers of 4-0 silk (Fig. 8-17). A strap muscle is used to buttress the esophageal closure and as a flap of vascularized tissue interposed between the esophageal and tracheal suture lines (Fig. 8-18). An end-to-end tracheal anastomosis is then performed. It may be necessary to repair the defect partially in the posterior membranous wall with a vertical suture line to limit the amount of

FIGURE 8-17 ■ The esophageal defect is closed in layers. **A**, The first layer closes the esophageal mucosa. **B**, The esophageal muscle is closed over the first layer. (From Mathisen DJ, Grillo HC, Wain JC, et al: Management of acquired nonmalignant tracheoesophageal fistula. *Ann Thorac Surg* 52:759–765, 1991. Reprinted with permission from the Society of Thoracic Surgeons.)

tracheal resection needed to treat a large fistula. In cases of extensive tracheal destruction, when end-to-end anastomosis may not be feasible, closure of the airway over a T-tube may be a valid alternative. Occasionally, there may be only insignificant damage to the trachea; a simple esophageal and tracheal repair with a muscle buttress would then be performed.

AIRWAY REPLACEMENT

When assessing surgical resectability of any tracheal lesions no clear guidelines of maximum tumor dimensions allowing for safe reconstruction via direct end-to-end anastomosis exist. Multiple parameters including tumor

FIGURE 8-18 ■ A local strap muscle is used to buttress the esophageal closure and separate it from the suture line. (From Mathisen DJ, Grillo HC, Wain JC, et al: Management of acquired nonmalignant tracheoesophageal fistula. *Ann Thorac Surg* 52:759–765, 1991. extent, body habitus, age, and surgeon experience have to factor in the decision to proceed with an attempted resection. In our experience, in patients treated for adenoid cystic carcinoma (ACC) or squamous cell carcinoma (SCC), complete resection is associated with higher survival compared with incomplete or no resection.³² A multicenter retrospective study confirmed that patients who had complete resection had a higher 5-year survival (55%) compared with incomplete resection (25%).³³ Radiation treatment may delay disease progression for up to 2 years in SCC or 5 to 7 years in ACC, but recurrence inevitably occurs.³⁴ While resection with curative intent is the optimal treatment, a subgroup of patients has to be treated nonoperatively because of the length of airway involvement. In our experience, 25% of patients with ACC and 33% of patients with SCC were deemed unresectable on preoperative evaluation.

Tracheal replacement grafts could offer a surgical option for patients in whom end-to-end anastomosis cannot be performed safely. Several strategies have been explored, including allotransplantation, synthetic materials, and tissue-engineered grafts. Although successful allotransplantation has been reported, the need for chronic immunosuppression to prevent graft rejection and graft failure limits its therapeutic potential in an oncologic patient population.³⁵ Successful two-stage tracheal allotransplantation after indirect revascularization in heterotopic location and subsequent withdrawal of immunosuppression has been reported in one case.³⁶ In a follow-up study by the same group, withdrawal of immunosuppression led to graft rejection and necrosis in four subsequent patients, indicating that transplanted allogeneic airway remains immunogenic and requires

chronic immunosuppressive treatment to maintain graft viability and integrity.³⁷

Cryopreserved aortic homografts were examined extensively in large animal models of tracheal replacement and have reached clinical application in several cases.^{38,39,40} However, short- and long-term mechanical stability of cadaveric aorta was not sufficient, and stenting was required to maintain airway patency. In two reported cases, anastomotic dehiscence and subsequent mediastinitis led to a poor outcome. To address mechanical stability and need for immediate perfusion, especially in the setting of a tissue graft exposed to the nonsterile tracheobronchial tree, experimental models of composite tissue grafts featuring cartilage reinforcement and tissue wrapping have been reported.⁴¹ We recently reported our experience with laryngeal reconstruction for airway reconstruction after partial laryngectomy with cryopreserved aortic homografts.⁴² In this series, 15 patients underwent single-stage wide-field transcervical partial laryngectomy with subsequent cryopreserved aortic homograft reconstruction, thereby avoiding total laryngectomy. In this approach, the reconstructed field was in the neck rather than the chest, well-vascularized tissue was available to support rapid revascularization, and covered defects were partial rather than circumferential. At follow-up, all patients were decannulated successfully and had laryngeal phonation.

Recent reports of tissue engineered tracheal grafts have fueled the enthusiasm for personalized, regenerated tissue grafts for tracheal replacement. Based on the concept of combining a biologic or synthetic scaffold material with viable, patient-derived cells and growth factors, various grafts have been generated and reached the stage of investigational clinical application. Several case reports describe the use of decellularized trachea and synthetic scaffold materials that were repopulated with patient derived cells and used successfully to replace circumferential airway defects.^{43,44,45} Similar to aortic homografts, these engineered tissues struggle with short and long-term mechanical stability, and the lack of immediate perfusion, but on long-term follow-up appear to incorporate and achieve acceptable airway stability and patency. Systematic evaluation of various scaffold materials, cell seeding and culture strategies, and surgical implantation technique will be required to generate clinical protocols for broader use of tissue engineered tracheal replacement grafts.

All tracheal replacement grafts face similar challenges. Immediately after implantation, any graft tissue is in direct contact with the outside world, creating risk for epithelial damage (in the case for viable grafts), infection, and subsequent anastomotic failure. In addition, short- and long-term mechanical integrity of the implanted graft has to be maintained to allow early weaning from mechanical support and extubation, prevent airway collapse, and avoid the need for airway stenting.

PERIOPERATIVE MANAGEMENT

The goals of both intraoperative and postoperative care are the promotion of anastomotic healing and the

maintenance of good pulmonary toilet. Ideally, patients are extubated in the operating room. The need for postoperative ventilation is a contraindication to tracheal resection. Patients with marginal lung function need careful management during the operation to help avoid the need for postoperative mechanical ventilation. During the procedure, secretions and blood are kept from contaminating the distal tracheobronchial tree, and volume overload is avoided. Rarely, an especially high laryngotracheal resection will cause enough laryngeal edema to necessitate 24 hours of steroids to avoid impending reintubation and tracheostomy. In these cases, it is recommended to give 10 mg of dexamethasone (Decadron) intravenously, then 4 mg every 6 hours. Heliox, with its low viscosity, is sometimes useful in these circumstances, as it can occasionally assist in gaining enough time for the other maneuvers to take effect. The patient is cautioned against unnecessary speech during this period, because it can contribute to the laryngeal edema. Diuresis and elevation of the head of the bed are important to diminish edema. Postoperatively, patients are supplied with humidity through a face mask to facilitate clearance of secretions. Most patients are able to clear their airway by coughing. Frequently, therapeutic flexible bronchoscopy is performed to suction secretions under direct vision. Cervical flexion is maintained with the chin-to-chest suture for 5 to 7 days, after which the patient is advised not to extend the neck for another week. Before removing the chin-to-chest suture, we routinely examine the anastomosis with a flexible bronchoscope to ensure normal healing. Oral alimentation is begun cautiously in the first few postoperative days.

RESULTS

Postintubation tracheal injuries remain the most common indication for tracheal resection and reconstruction, despite definition of the etiology of these lesions and development of techniques to avoid them. In 1995, we reported 503 patients who underwent tracheal resection and reconstruction for postintubation lesions.⁴⁶ The balloon cuff of an endotracheal or tracheostomy tube accounted for 251 lesions, 178 lesions were at the site of a tracheostomy, and 38 patients had evidence of both lesions. In 36 patients, the exact site was uncertain, often because of prior attempts at treatment, including multiple tracheostomies. Of the 503 patients, 441 had lesions that were isolated to the trachea, and 62 had concomitant involvement of the subglottic larynx.

Many patients had undergone prior attempts at surgical treatment before referral. These attempts included resection ($n = 53$), tracheal operations such as wedge resection, splinting, or fissure ($n = 31$), and laryngeal procedures such as stenting, grafting, or fissure ($n = 20$). Sixty had had T-tubes placed, and at least 45 had suffered laser treatment. Eight patients had prior repairs of tracheoesophageal fistulas, three of which had failed.

The initial procedure was performed through a cervical incision in 350 patients. In 145 patients, a partial upper sternal division through the sternal angle was used, and two more patients required the addition of right

anterior thoracotomy to this approach. Six patients underwent repair via a high posterolateral thoracotomy. The amount of trachea resected ranged from 1.0 to 7.5 cm and was usually 2 to 4 cm.

Of the 503 initial patients, 324 underwent a trachea-to-trachea anastomosis, and in 117 patients the reconstruction involved partial resection of the cricoid cartilage with laryngotracheal anastomosis. In the total series of 503 patients, 9.7% underwent laryngeal release procedures. However, only 8% of the 450 patients who had not undergone previous tracheal resection and reconstruction required a laryngeal release, in comparison with 24.5% of the 53 who had prior resection and reconstruction. Many in the former group represent our earlier experience in tracheal surgery. Only one patient required intrapericardial hilar release.

The results have been classified as good, satisfactory, failure, and death. The result is described as *good* if the patient is functionally able to perform usual activities and if postoperative roentgenograms or bronchoscopic examinations show an anatomically good airway. Patients are placed in the *satisfactory* category if they can perform normal activities, but are stressed on exercise; this is also applied, in the absence of symptoms, to those with abnormalities involving the vocal cords or those with significant airway narrowing evident on either endoscopic or roentgenologic examination. *Failure* indicated the need for a permanent tracheostomy or T-tube. The average length of follow-up was 3 years. The results were good in 440 patients, satisfactory in 31 patients, and there were 20 failures and 12 deaths. Failure was treated with tracheostomy ($n = 11$), T-tube ($n = 7$), or dilations ($n = 2$).

In experienced hands, laryngotracheal resection and reconstruction is associated with excellent results and minor complications. The results of single-staged laryngotracheal resection for idiopathic laryngotracheal stenosis were initially reported by Grillo and colleagues⁴⁷ and have been updated to include a series of 73 patients.⁴⁸ The majority of these patients were women (71/73), with a mean age of 46 years (range, 13 to 74 years). Twenty-eight patients (38%) had undergone a previous laser, dilation, laryngeal, or tracheostomy procedure. After laryngotracheal resection, the majority of patients (67/73) were extubated in the operating room, and 7 required temporary tracheostomies, with only 1 in the last 30 cases. All patients were successfully decannulated. There was no perioperative mortality. The principal morbidity was alteration in voice quality, which improved with time. Sixty-seven (91%) required no further intervention for idiopathic laryngotracheal stenosis. Six patients required at least one bronchoscopy for granulation tissue or dilation (or both), and progression of disease was observed in only one patient. In our current experience, none of the last 100 patients required tracheostomy. In a subgroup of patients with idiopathic subglottic laryngotracheal stenosis, side-to-side narrowing poses a challenge for successful reconstruction.²⁷ In 2009, we reported a series of 18 patients in whom the standard technique of anterior cricoid resection was modified to specifically address the small ventricle. By performing a tailored cricoplasty in addition to resecting the anterior portion of the cricoid—that is, resecting and resurfacing the inner

third to half of the lateral cricoid cartilage—we achieved horizontal enlargement of 3 to 5 mm and thereby increased the side-to-side dimensions of the resulting subglottic airway. Functional postoperative outcome was excellent with overall satisfaction at follow-up of resting and exertional dyspnea at 9.7 and 9.5, respectively, on a 10-point scale.

The results from the repair of tracheoesophageal fistulas (TEFs) were reported in a series of 38 patients in whom 41 operations were performed.³¹ Simple division and closure of the fistula were performed in nine patients. Tracheal resection and reconstruction were combined with esophageal repair in the remainder. The esophageal defect was closed in two layers, and a viable strap muscle was interposed between the airway and esophageal suture lines in all cases. There were four deaths (10.9%); three of these occurred after attempted transthoracic repair of distal tracheoesophageal fistulas. Three patients developed recurrent fistulas and one patient suffered a delayed tracheal stenosis. All were successfully treated with reoperation. Of the 34 survivors, 33 can swallow normally and 32 breathe without the need for a tracheal appliance. We recently updated this series with an additional 36 patients undergoing surgical repair from 1992 to 2010.⁴⁹ The incidence of complex TEF after esophagectomy and laryngectomy has increased, while postintubation TEF has become less prevalent. Correspondingly, airway resection and reconstructions were performed in fewer patients (54%) than in the earlier series (75%). Despite the technical challenges of TEF repairs after anastomotic leak, airway ischemia, or prior failed attempts of repair, the surgical principles involved in their closure remain the same. Interposition of robust vascular tissue and separation of suture lines are even more important in reoperations.

For the oncologic results of primary tumors of the trachea, 208 patients were evaluated in a retrospective multicenter study.⁵⁰ Histologic types included 94 squamous cell carcinomas, 4 adenocarcinomas, 65 adenoid cystic carcinomas, and 45 miscellaneous tumors. The procedures performed consisted of 19 laryngotracheal, 165 tracheal, and 24 carinal resections. Operative mortality was 10.5%. As expected, long-term survival was significantly better for ACC than for SCC, with 73% versus 47% at 5 years, and 57% versus 36% at 10 years, respectively.

Gaissert and coworkers⁵¹ published the 40-year cumulative Massachusetts General Hospital experience of treating primary adenoid cystic and squamous cell carcinomas of the trachea. During this period, 270 patients were evaluated, with histologic distribution equally distributed between ACCs and SCCs. Resection was performed in 191 patients (71%), with an operative mortality of 7.3% (14/191). Importantly, both rates of resection and hospital mortality have improved each decade. As this center's experience has grown, operative mortality has decreased from 21% in the 1960s to 3% in the decade preceding the report.

Resection was not performed in 79 patients—34 patients with ACC (25%) and 45 patients with SCC (33%). Contraindications to resection included tumor length (67%) and locoregional extent (24%) in the vast

majority of cases, with distant metastases only rarely present (7%). The determination of unresectability was made during operative exploration in 17 of 208 patients (8%). ACC lesions tended to be longer and to be associated with more significant locoregional extension. This explains the more frequent observation of ACC resections having positive microscopic tracheal and radial margins (59%) when compared with SCC (18%).

The overall survival for all patients with primary tracheal carcinoma was 84% at 1 year, 45% at 5 years, and 25% at 10 years. Mean survival was 38 months for resected SCC, 8.8 months for unresectable SCC, 69 months for resected ACC, and 41 months for unresectable ACC. Notably, survival in patients with ACC after incomplete resection was still 14.5% at 15 years. Multivariate analysis identified ACC and complete resection to be associated with 5-year survival, and ACC, complete resection, and age to be associated with 10-year survival. Tumor length, lymph node status, or type of resection did not influence long-term survival.

The presence of tumor at the resection margins of ACC, even by frozen section during operation, has particular importance in airway reconstruction. The surgeon must often compromise complete resection for safety, and the data just cited indicate that a small, though not statistically significant, survival benefit exists in these patients. All these patients now receive postoperative irradiation. Suture line recurrence thus far has been rare, and late recurrence has been related to distant disease. In contrast, irradiation of unresected tumor is all but uniformly characterized by local recurrence in 3 to 5 years despite early good response.

Secondary cancers arising in the thyroid and invading the trachea have also been resected with good results. Of 27 patients undergoing resection and reconstruction of the trachea for thyroid cancer invading the airway, including patients with both simple and complex laryngotracheal reconstructions, two died in the postoperative period, one had a short segment of tracheal necrosis requiring reoperation, and all others were provided with an adequate airway by their initial operation. Only two patients experienced an airway recurrence.¹⁷ This series was recently updated to include 82 patients treated at the Massachusetts General Hospital.⁵² There were no additional operative mortalities in this expanded series. With mean follow-up at greater than 6 years, mean survival was 9.4 years and 10-year survival was 40%.

COMPLICATIONS

Complications after tracheal surgery are similar regardless of the problem for which resection and reconstruction is performed. In 2004, Wright and colleagues⁵³ presented the most complete analysis of anastomotic complications after tracheal resection. This review of 901 patients identifies relevant risk factors for the development of these problems and further describes their management. Anastomotic complications include granulations at the suture line, stenosis, and tracheal separation.

A significant reduction in suture granuloma formation has been seen since the conversion to absorbable suture

material used for the anastomosis. In fact, the use of absorbable Vicryl sutures since 1978 has all but eliminated suture-related granulations. These granulations can be successfully managed with bronchoscopic suture removal and local steroid injection. Extensive processes may require reoperation for resection or placement of a T-tube or tracheostomy.

Several predictors of anastomotic complications were demonstrated: reoperation, diabetes, lengthy (>4 cm) resections, laryngotracheal resections, age less than 17 years, and need for a tracheostomy before operation. The frequency of anastomotic complications was higher in patients undergoing operations for tracheoesophageal fistula than in those with tracheal tumors, postintubation stenoses, and idiopathic laryngotracheal stenoses. Of note, corticosteroid use was not associated with an increased complication rate, probably because of the management strategy used for this group, which is to defer tracheal operations in the presence of high-dose steroids until they can be effectively tapered.

Overall, 81 patients experienced anastomotic complications in this series. Thirty-seven patients had separation of the suture line, 37 patients developed anastomotic stenosis, and 7 patients had airway obstruction from granulation tissue formation. Complications were treated with multiple dilations ($n = 2$), temporary tracheostomy ($n = 7$) or tracheal T-tube ($n = 16$), permanent tracheostomy ($n = 14$) or T-tube ($n = 20$), and reoperation ($n = 16$). The mortality of patients who had anastomotic complications was 7.4% (6/81), compared with 0.06% (5/820) in those without anastomotic complications. In this series, no patient has died since 1988. This success can be attributed to the routine use of postoperative bronchoscopy, and the early recognition and subsequent definitive management of anastomotic complications.

We have had experience with four patients who developed anastomotic complications with varying degrees of ischemic cartilage necrosis. Presentation ranged from subcutaneous emphysema, cellulitis, to bronchoscopic evidence of partial cartilaginous loss. All patients had strap muscles carefully sutured to the anastomosis at the time of reconstruction. All patients were assessed for airway integrity and deemed stable. Patients were treated with intravenous antibiotics, inhaled tobramycin nebulizers, and inhaled heliox if any shortness of breath was experienced. All four patients underwent treatment with hyperbaric oxygen to increase tissue partial oxygen pressure and to improve wound healing. Patients generally received 20 treatments of hyperbaric oxygen administered twice daily. All patients healed without the need for tracheostomy or T-tubes. All patients remained asymptomatic with only minor narrowing seen on radiographs. Consideration for this approach should be given if evidence of tissue necrosis is seen on postoperative bronchoscopy, and airway stability can be assured.⁵⁴

SUMMARY

Some of the most challenging problems facing thoracic surgeons include benign strictures arising from postintubation stenosis or idiopathic laryngotracheal stenosis,

fistulas from the trachea to the esophagus or innominate artery, and primary or secondary tumors of the trachea. Bronchoscopic evaluation is essential to ascertain the diagnosis and in preoperative planning. If critical airway stenosis is suspected, flexible bronchoscopy should be performed only in an operative suite where a rigid bronchoscope is available in case the airway needs to be reestablished. An anesthesia team familiar with the techniques of cross-table ventilation and capable of an interactive team approach is essential.

All patients with tracheal lesions, from benign strictures to malignant tumors, deserve serious consideration for definitive resection. Nonsurgical methods such as dilation, ablation, or stenting are palliative and should be used only as temporizing maneuvers or in poor surgical candidates. Deciding whether a lesion is resectable requires mature surgical judgment. Postoperative radiation should be given to all patients with resected squamous cell or adenoid cystic carcinomas. Patients with thyroid cancer secondarily invading the trachea should be considered for tracheal resection, even with advanced disease, to avoid fatal loss of the airway. With an experienced team, most patients can be treated successfully with a single-stage tracheal resection with low morbidity and mortality and excellent long-term results.

Azygos Lobe
Horseshoe Lung
Bronchogenic Cysts

LUNG BUD ANOMALIES

Pulmonary Agenesis, Aplasia, and Hypoplasia

Congenital Lobar Emphysema

Congenital Parenchymal Cysts

Congenital Cystic Adenomatoid Malformation

Infantile Pulmonary Emphysema

Polyalveolar Lobe

Pulmonary Lymphangiectasia

VASCULAR ABNORMALITIES

Unilateral Absence of a Main Pulmonary Artery

Idiopathic, Hyperlucent Lung Syndrome (Swyer-James or Macleod Syndrome)

Pulmonary Artery Sling

Isolated Pulmonary Artery Aneurysm

Dysphagia Lusoria

Pulmonary Vein Abnormalities

Pulmonary Varix

Pulmonary Arteriovenous Malformations

CONCLUSION

Various congenital abnormalities involve the pulmonary system. Some of these result in arrested development and stillbirth. Some infants survive delivery only to die shortly thereafter. Neonates with severe anomalies typically display dyspnea and cyanosis at birth. Older children with less critical anomalies may have feeding problems, respiratory infections, developmental delays, or activity limitations. For neonates who are in respiratory distress, speed of diagnosis and early treatment are critical. Intubation may be life-saving. Examination of the naso-oropharynx, neck, and chest along with an emergent radiograph allows rapid diagnosis in most cases. Quality computed tomography (CT) may be necessary to delineate the anomaly. Other important adjuncts that may enhance diagnostic speed and accuracy are echocardiography, magnetic resonance imaging (MRI), and endoscopy.

During the past decade, improvements in prenatal diagnosis¹ have allowed intrauterine repair of some defects.² With non-life-sustaining defects such as anencephaly and renal agenesis, parents may opt for pregnancy termination. For potentially correctable lesions,

the pregnant mother can be transferred to a tertiary medical center. Advanced supportive and surgical techniques have led to improved survival in these infants.

HISTORY

The first report of a congenital lung defect was by Fontanus in 1639,³ describing an infant with a lung cyst. In 1777, Huber⁴ described an infant with an intralobar sequestration, with blood supply from the thoracic aorta. In the mid-1800s, an extralobar (Rokitansky lobe) sequestration was reported. The neonatal prevalence of lung infections in the 1900s was so high that it was difficult to formulate concepts of congenital lung disease, and the technology was not sufficiently advanced to correct such defects. In 1917, Gladstone and Cockayne theorized how sequestrations occurred, and in 1925, Koontz reviewed congenital pulmonary cystic diseases. The first surgical correction of a congenital lung anomaly was performed by Rienhoff⁵ in 1933, that being local lung cyst excision

in a 3-year-old boy.⁶ Gross and Lewis⁷ performed the first pediatric lobectomy in a child with congenital lobar emphysema. Cystic disease in the right upper and right middle lobes was resected by lobectomy in 1943.⁸ In 1946, Gross⁹ performed a pneumonectomy in a 3-year-old with cystic lung disease. Potts performed the first neonatal lobectomy in 1949. Lewis later reported the death of a child on whom a lobectomy was being performed for intralobar sequestration, citing exsanguination after lost control of the systemic feeding artery. With development of advanced supportive, anesthetic, vascular, and bypass techniques, the mortality rate for children at high risk for congenital lesions has significantly decreased.

EMBRYOLOGY

Lung development occurs both prenatally and postnatally and continues into adulthood. Intrauterine pulmonary development is divided into four phases: embryonic, weeks 1 to 5; pseudoglandular, weeks 5 to 16; canalicular, weeks 16 to 26; and terminal sac, weeks 26 to birth.¹⁰⁻¹²

During the embryonic phase, the foregut begins to develop from the embryonic endoderm beginning on day 9, and the median pharyngeal groove develops from the foregut on day 22. At approximately 4 weeks of gestational age, the respiratory diverticulum, or lung bud, emerges as a 3-mm outpouching from the ventral wall of the embryonic foregut. The respiratory diverticulum at this stage is surrounded by splanchnic mesenchyme that later gives rise to the visceral pleura. Concurrently, the lateral mesoderm grows to form the tracheoesophageal septum, effectively separating the tissues that will become the lung from those that will become the esophagus. The lung bud initially forms the trachea, followed by two bronchial buds that enlarge to form the right and left main bronchi by the start of the fifth week. The individual five lobes become evident during the next few weeks.

In the pseudoglandular stage (weeks 5 to 16), the bronchial tree develops, including the cuboidal and columnar epithelial layers and cartilaginous rings. Repetitive branching of the bronchial tree during this stage gives rise to all the conducting airways. The pulmonary vasculature develops in tandem with the airways; however, the airways and pulmonary arterial branches remain separated by mesenchyme. By the 16th week, the bronchial tree and the pulmonary arteries are fully formed, and the common pulmonary vein drains into the sinoatrial region of the heart.

In the canalicular phase (weeks 16 to 26), respiratory bronchioles divide to form alveolar ducts, and the mesenchymal separation of the airways from pulmonary arterial branches begins to recede, allowing the first appearance of the air-blood barrier. By the 25th week, the pulmonary venous drainage has completely developed.

The terminal sac period (weeks 26 to 40) is marked by continued extension of the air-blood barrier. The primitive alveoli proliferate and become intimately involved with the surrounding capillaries as the mesenchyme

separating them thins out. Terminal sac formation from the terminal lung buds occurs in a coordinated interaction between promoter factors, such as fibroblast growth factor 10, and inhibitory factors, such as Sonic hedgehog and transforming growth factor β .¹³⁻¹⁵ Mechanical fluid pressure on the terminal lung bud also appears to play a critical role.^{11,16,17} The adult form of alveoli has developed by the 30th to the 36th week, and the airways are almost fully developed before term. Type II pneumocytes produce surfactant in preparation for delivery.

Lung development continues postnatally with alveolar multiplication that results from progressive septation within the terminal sacs. Septation is driven by transcription factors, growth factors, and extracellular matrix molecules and is closely tied to sprouting angiogenesis (under the influence of vascular endothelial growth factor), followed by the splitting and remodeling of alveolar capillaries. Immediately after birth, alveoli are fairly thick walled and number approximately 20 million, less than 10% of their eventual number. Acinar development continues to the eighth year of life, but the rate of development diminishes after the second to fourth years. By the end of the eighth year, there are approximately 300 million acini, and after the tenth year of life, alveoli enlarge rather than increase in number. The lung-environmental interface increases from 3 to 4 m² at birth to 75 m² in adults. From birth to the age of 5 years, airway diameter increases; after the age of 5 years, the proximal airway grows at a faster rate than the more distal airways. The trachea is initially funnel-like but becomes more cylindrical by the age of 4 years. Pulmonary vessel length and diameter rapidly increase until 18 months of age.

Normal airway and vascular development depends on a variety of factors. These include cell-to-cell interactions, local and systemic hormones and growth factors, central and peripheral neural influences, and chest wall effects. The latter involve contact influences of the bony and muscular structures. Alterations in normal development may result from defects in any of these factors. Viral infection, hypoxia, starvation, and teratogens also may disrupt normal lung development. In utero airway obstruction may produce a variety of lesions.¹⁸ Of these patients, 84% have additional nonpulmonary anomalies.¹⁹

Three major hypotheses have been formulated to explain the pathogenesis of anomalous tracheobronchial development.^{20,21}

1. The *reduction theory* postulates that the final anatomy is the result of shrinkage and finally suppression of portions of a primitive pattern encompassing all the components of the extant mammalian bronchial distribution.
2. The *migration theory* considers that bronchial outgrowths have the potential of migrating from their initial locus to new points of origin of a bronchus or the trachea.
3. The *selection theory* advocates local disturbances in the development during budding of the bronchial buds under the influence of bronchial mesenchyme.²²

Lung resection in neonates and children is fairly well tolerated. Anatomy is easily defined because there is less

mediastinal and hilar fat, adenopathy, and scarring from chronic disease compared with adults. Outcomes after pediatric lung resection are good. Children younger than 5 years develop new alveoli after resection. In those older than 5 to 10 years, the alveoli enlarge, although they no longer increase in number. In an infant pneumonectomy model, lung function returns to normal within 9 to 12 months.²³⁻²⁵ Emphysematous changes do occur, as in adults. After lung resection in children in whom the remaining lung is normal, the child appears to grow, develop, and perform normally with maximal exercise.^{24,25} The diffusion capacity for carbon monoxide is reduced and pulmonary artery pressure increases with exercise, but pulmonary vascular resistance is normal after resection.²⁶

TRACHEAL ABNORMALITIES

Tracheal Agenesis and Atresia

Payne²⁷ first described congenital absence of the trachea in 1900. Fewer than 150 cases have been reported.²⁸ It represents a partial or complete absence of the trachea below the level of the normal larynx. This abnormality is incompatible with life if there is no connection of trachea or bronchi to the esophagus.²⁹ Floyd and others^{30,31} classified three distinct types of tracheal agenesis (Fig. 9-1). In type I, the trachea originates from the esophagus, and the distal trachea, including the carina, is fairly normal. Type I represents 10% to 13% of the total number of tracheal agenesis cases. In type II, the trachea and carina

are fused to the esophagus, and there is no residual trachea. Type II represents 59% to 62% of the total. In type III, the left and right mainstem bronchi originate from the esophagus, and there is no carina. Type III represents 22% to 31% of the total. Male incidence predominates in a 2:1 ratio. In 90% of the cases, there are other congenital lesions.³² Tracheal agenesis may be associated with VACTERL (vertebral, anal, cardiac, tracheal, esophageal, renal, and limb patterns of congenital anomalies)³³ or with complex congenital heart defects as well as with upper extremity defects and duodenal atresia (referred to as TACRD).³⁴ It is believed that tracheal agenesis is the result of developmental failure of the laryngeal tracheal bud at the third to sixth week of development. The tracheoesophageal septum fails to develop normally.³⁵ Antenatal diagnosis of tracheal agenesis offers the best chance of early treatment. The usual findings include polyhydramnios, fluid-filled and dilated esophagus, distended lungs, an inverted diaphragm, and fetal hydrops. Many of these features are similar to those found in congenital high airway obstruction syndrome (CHAOS), thus suggesting that these abnormalities may be components of the same spectrum and differing only in severity and extent. It is important to differentiate between tracheal agenesis/atresia and CHAOS because ex utero intrapartum treatment (EXIT) may be life-saving for CHAOS but has not been described for tracheal atresia.^{36,37}

Neonates usually present with a triad of severe respiratory distress, the inability to cry, and the inability to be intubated.³⁷ Survival is unlikely, although there are a few cases of survival reported in the literature.^{38,39} Those who are successfully managed are endoesophageally intubated,⁴⁰ with a nasogastric tube alongside the endotracheal tube for gastric decompression. Urgent bronchoscopy or tracheostomy can assist in diagnosis.^{41,42} CT scan is the procedure of choice for delineating the anatomy in a newborn.⁴³ A survivor is described who had a type II defect and underwent esophageal intubation, gastrostomy, and distal esophageal banding.³⁸ The patient is reported to have survived to 4 years, undergoing a colonic interposition at 3 years of age. A second patient is described with a type I defect who survived to 6 years of age.³⁹ Extracorporeal membrane oxygenation (ECMO) may temporize these patients until a more definitive solution can be achieved.⁴⁴ If the patients can be stabilized, they should be examined for other life-threatening defects, such as neural and cardiac anomalies, that may require correction. The gastroesophageal continuity can be corrected with colonic interposition or gastric conduit, but there have been no attempts to reconstruct the trachea. Perhaps, for the future, to reconstruct the incompletely developed airway, tracheal allografts⁴⁵ or tissue-engineered replacements⁴⁶ may be used for long-term success.

FIGURE 9-1 ■ Tracheal agenesis classification. There are three types of tracheal agenesis: type I, the trachea originates from the esophagus rather than from the larynx; type II, no trachea is present and the carina originates from the esophagus; and type III, each mainstem bronchus originates from the esophagus. (Modified from Haben CM, Rappaport JM, Clarke KD: Tracheal agenesis. *J Am Coll Surg* 194:217-222, 2002.)

Congenital Tracheal Stenosis

Congenital tracheal stenosis (Fig. 9-2) is rare. Cantrell and Guild⁴⁷ described three forms of stenosis. Type I is stenosis of the full length of the trachea. Type II is a funnel-shaped stenosis of the upper, lower, or entire

FIGURE 9-2 ■ Tracheal stenosis (stovepipe trachea) in a 20-month-old boy with stridor since birth. Frontal chest radiograph shows a diffusely narrowed trachea faintly outlined by water-soluble contrast medium. (Courtesy Simon C. Kao, MD, Iowa City, IA.)

trachea. Type III is a segmental stenosis of the lower trachea. This classification assists in identifying patients who are more likely to have associated anomalies and in planning treatment. Stenotic regions have complete cartilaginous rings, the number of which is variable, anywhere from 2 to 18. This rare anomaly is associated with pulmonary vascular sling or vascular ring in 50% of cases.⁴⁸ A functional classification system has been proposed to assist in selection of the operative candidate.^{49,50}

These patients usually have exertional wheezing or stridor after birth. The type II and type III abnormalities are associated with anomalous location of one or more bronchi, most likely a left pulmonary artery sling. All three types are associated with pulmonary agenesis. A new morphologic classification has been proposed and is based on the bronchial arborization pattern, thus introducing the term *congenital tracheobronchial stenosis*.⁵¹ Symptoms vary according to the degree of stenosis. Patients presenting during the neonatal period or infancy with severe stridor, cyanosis, and recurrent stridor have the highest mortality rate. Many of these patients have associated congenital malformations and infections. Their prognosis, even after surgical correction, is variable.⁴⁹ Older children presenting at 1 year of age or soon thereafter have a surgical mortality rate of 10% to 20%.⁵² Some children, late in childhood or early teens, may present for an evaluation for asthma with varying degrees of exertional dyspnea. Typically, these children have a better prognosis. CT, especially multidetector CT, works better than flexible bronchoscopy⁵³ because it provides enough detail to not only assess the tracheobronchial abnormality with a sensitivity of 90% but also to assess any associated anomalies. Bronchoscopy aids in diagnosis, treatment planning, and evaluation of the surgical repair intraoperatively and postoperatively. Echocardiography is helpful to assess for cardiac and vascular

anomalies. Patients should be aggressively treated because, without surgical correction, they are at high risk for sudden death.⁵⁴ Partial tracheal resection is the most frequently performed operation. The neonatal trachea does not tolerate tension as well as the adult trachea.⁵⁵ Up to 50% of the infant trachea can be resected with primary reanastomosis. The repair is much more difficult if more than 50% of the trachea or the carina is involved.

In 1964, the first repair, a primary resection and end-to-end anastomosis, was reported by Cantrell and Guild.⁴⁷ Reconstruction has been performed with pericardium,⁵⁶ aortic homograft,⁵⁷ costochondral graft,⁵⁸ slide tracheoplasty (Fig. 9-3),^{59,60} and tracheal autograft.⁶¹ Complete repair of the tracheal stenosis and any vascular ring or sling requires cardiopulmonary bypass and potential circulatory arrest. Backer and coworkers⁶² reviewed their 18-year experience in 50 patients, comparing four tracheal stenosis repair techniques¹: pericardial patch,² primary resection,³ tracheal autograft, and slide tracheoplasty.⁴ They concluded that when eight or fewer rings are involved, primary resection is preferable. For stenosis longer than eight rings, an autograft is better. Vascular endothelial growth factor application has the potential of improving the results of tracheal autograft.⁶³ In contrast, Muraji and coworkers⁶⁴ demonstrated that the slide tracheoplasty technique allowed early extubation and an excellent long-term result in one case. Currently, slide tracheoplasty is the operation of choice for long-segment tracheal stenosis.⁵¹ ECMO may be necessary to support the neonate postoperatively.^{44,58} Long-term outcome after resection appears to result in normal growth and development.⁶⁵ For patients who are considered surgically uncorrectable, palliative maneuvers include balloon dilation and split posterior tracheoplasty,⁶⁶⁻⁶⁸ stenting, local steroid injection, electroresection, and cryotherapy.^{49,50}

Tracheomalacia

In tracheomalacia, weakened cartilage collapses on expiration. With inspiration, there is sufficient suspension of the tracheal wall to maintain patency. The most common pathologic finding is oval rather than round cartilaginous rings. There are both congenital and acquired forms of tracheomalacia. The congenital form can be diffuse and both proximal and distal, involving the mainstem bronchi; it is associated with tracheoesophageal fistula.^{69,70} The more common, acquired form results from degeneration of the cartilaginous support, usually by vascular compression such as from a vascular ring or sling, adjacent inflammatory process, tumor, or chest wall deformity (e.g., pectus excavatum).

Tracheomalacia is not usually manifested at birth. It worsens as the child grows, usually after several weeks of life. Coughing, respiratory distress, severe dyspnea, stridor, and cyanosis can occur. Acute apnea, referred to as “dying spells,” is the most severe presentation. Dyspnea worsens with agitation or respiratory tract infections. These severe symptoms should prompt further investigation.

One fourth of all patients with esophageal atresia have tracheomalacia. Tracheoscopy, bronchoscopy,

FIGURE 9-3 ■ Congenital tracheal stenosis. **A**, After identification of the area of stenosis, the midportion of the stenosis is transected, leaving two halves of the trachea disconnected. **B**, A longitudinal tracheal incision is then made in each half, the full length of the stenosis, posterior in the upper half and anterior in the lower half. The corners are trimmed to allow an even, uncrimped anastomosis. **C**, Stay sutures help in retraction and alignment. **D** and **E**, The anastomosis results in an oblique suture line. The resultant cross-sectional area is quadrupled. (Modified from the Society of Thoracic Surgeons. Grillo HC: Slide tracheoplasty for long-segment congenital tracheal stenosis. *Ann Thorac Surg* 58(3):613–619, discussion 619–621, 1994.)

esophagoscopy, and esophagography may be necessary for complete evaluation. CT and MRI provide additional information. The differential diagnosis includes normal pulsatile collapse, bronchial webs, and tracheal tumors. Many patients suspected of having tracheomalacia may instead have gastroesophageal reflux disease or reflux disease in addition to tracheomalacia. This may warrant either a trial of a proton pump inhibitor and prokinetic agent or a formal evaluation for reflux.⁷¹

Tracheomalacia improves with age in most cases. Dying spells (acute life-threatening events), inability to be weaned from the ventilator, and failure to thrive are indications for more aggressive therapy. If tracheomalacia is mild, the infant should be supported and observed because infants usually outgrow their tracheomalacia

within the next 2 years. In more severe forms, the mortality rate is as high as 80% with conservative management. Stents have been used with varying success to allow cartilage maturation; this usually takes several months.^{72,73} Tracheostomy also has been used but is associated with some complications.⁷⁴ Aortopexy (Fig. 9-4), by itself or with tracheal resection or stenting, has been performed by a left submammary thoracotomy through the third interspace or through a median sternotomy. The thymus is preserved. After exposure of the ascending aorta, three or four nonabsorbable sutures are placed through the aortic adventitia above and below the innominate artery takeoff. These sutures are attached to the periosteum. Finally, the endotracheal result is visualized by intraoperative bronchoscopy. By 4 weeks, 80% of the patients

FIGURE 9-4 ■ Tracheomalacia and aortopexy. In patients with severe tracheomalacia and aortopexy, suturing of the proximal transverse-ascending aorta to the anterior chest wall or sternum may significantly improve the obstructive symptoms. (Modified from Weber TR, Keller MS, Fiore A: Aortic suspension [aortopexy] for severe tracheomalacia in infants and children. *Am J Surg* 184:573–577, 2002.)

are extubated, and the long-term results are good.⁷⁵ The acquired form is treated similarly to the congenital form. Longer segment lesions without vascular compression often require tracheostomy and mechanical ventilation for a time. Bronchomalacia may require both aortopexy and pulmonary artery pexy.⁷⁶ The failure rate after aortopexy ranges between 10% and 15%.⁷⁷ Direct anterior tracheal suspension is gaining popularity. This is performed through a median sternotomy, and the space between the superior vena cava and the aorta is developed. Sutures are passed into the tracheal wall, brought out through the sternal tables, and tied under direct bronchoscopic visualization. Mitchell and colleagues report on 21 such procedures performed with excellent results.⁷⁷

BRONCHIAL BRANCHING ABNORMALITIES

Bronchial branching abnormalities are rarely symptomatic. Accessory bronchi can originate off the trachea or mainstem bronchi and may be attached to rudimentary lung. They are usually incidental findings at autopsy. Cervical diverticula present in utero may regress before birth. There are case reports of bronchi crossing the mediastinum to supply the opposite lung.^{22,78} Tracheal bronchus, or *bronchus suis*, is a congenital branching anomaly in which the bronchus arises directly from the trachea above the carina (Fig. 9-5). The most frequent tracheal bronchus is to the right upper lobe. These abnormalities may be isolated or associated with other tracheopulmonary anomalies. They can be associated with wheezing, stridor, pneumonia, bronchiectasis, and hemoptysis. Accessory bronchi and associated abnormal pulmonary tissue should be resected if symptomatic.⁷⁹ Chest radiography and high-resolution CT are helpful in defining the anomaly.^{80,81} Fiberoptic bronchoscopy, bronchoalveolar lavage, and biopsy have been used to evaluate the abnormality. Endobronchial aspiration,

lung resection, and transplantation have all been methods of treatment.²²

The following are anomalies that are more frequently symptomatic, potentially life-threatening, and possibly treatable.

Bronchial Atresia

Bronchial atresia, first described by Ramsay and Byron in 1953,⁸² is the second most common abnormality of the airway after tracheoesophageal fistula. A lobar or segmental bronchus ends blindly in the lung tissue. Lung tissue distal to the bronchial atresia expands and becomes emphysematous as a result of air entering through the intra-alveolar pores of Kohn and bronchoalveolar channels of Lambert.⁸³ Beyond the atretic segment but proximal to the hyperinflated lung, the terminal airway is filled with mucus. It is believed that the bronchial bud somehow separates distally from the proximal bronchial bud and continues to develop. Another potential explanation is that there is a vascular insult of the airway in the atretic segment. In either case, the distal airway continues to develop normally.

Infants usually develop respiratory distress 4 or 5 days to several weeks after birth. They may have wheezing, stridor, and repeated pulmonary infections. The most common location is in the left upper lobe, then the left lower lobe, followed by the right upper lobe. A segmental bronchus rather than a lobar bronchus is atretic, most frequently presenting as a lung mass on the first chest radiograph of the newborn. Fetal lung fluid is slowly absorbed, becoming a localized translucency with an opaque circular or oval density at the hilum. Patients rarely mature to adulthood without investigation.

For better assessment of this abnormality, a CT scan should be performed.^{84,85} Prenatal diagnosis by ultrasonography has been reported.⁸⁶ The differential diagnosis includes acquired bronchial stenosis (which may result from long-term intubation), bronchial adenoma, sequestration, mucoid impaction, vascular

FIGURE 9-5 ■ **A**, Coronal view of a computed tomography scan showing a tracheal bronchus. **B**, Bronchoscopic view of the origin of the right upper lobe bronchus from the trachea.

compression syndrome, Swyer-James syndrome, and atypical bronchogenic cyst.

Indications for resection in bronchial atresia include a recurrent and possibly serious pulmonary infection, respiratory distress, and increasing size of the translucent lung.⁸⁷ Some surgeons resect the abnormal tissue to prevent infection. Segmentectomy is possible, but lobectomy is usually required.

Congenital Bronchiectasis

Bronchiectasis is an abnormal dilation of the bronchi or bronchioles. It is thought to be secondary to failure of the mesenchyme to differentiate into cartilage and muscle.⁸⁸ It is not a specific disease entity per se, but the common end stage of a variety of pathophysiological processes. Cystic fibrosis, primary ciliary dyskinesia, Young syndrome, Williams-Campbell syndrome, α_1 -antitrypsin deficiency, and certain primary immune deficiency syndromes are associated with bronchiectasis. It results in a chronic, mildly productive cough with recurrent pneumonia. CT usually confirms the diagnosis,⁸⁹ and bronchoscopy typically is unnecessary. Bronchography is rarely necessary, given the detail provided by high-resolution CT. Treatment and prognosis depend on the number of segments or lobes involved. Patients are provided with humidity, chest physiotherapy, and oxygen, as

necessary. Therapeutic bronchoscopy is performed for suspected mucoid obstruction or bleeding. Bleeding is initially controlled by embolization, topical epinephrine, or intravenous pitressin. Oral, intravenous, and nebulized antibiotics may be helpful in controlling symptoms.⁹⁰ Patients who have localized congenital symptomatic bronchiectasis may require a segmentectomy, lobectomy, or possibly pneumonectomy. The success of surgical intervention is related to the ability to resect all the diseased lung.⁹¹

Tracheobronchomegaly (Mounier-Kuhn Syndrome)

Tracheobronchomegaly was first described in 1932 by Mounier-Kuhn.⁹² It is characterized by excessive dilation of the trachea and main bronchi (Fig. 9-6).⁹³ This dilation is the result of atrophy of the elastic tissue and smooth muscle of the trachea and mainstem airways.⁹⁴ Airway dilation continues to third-order subdivisions. During the course of the disease, mucosal herniations develop between tracheal rings, creating a diverticulosis pattern. Associated conditions include cutis laxa, Ehlers-Danlos syndrome, Marfan syndrome, Kenny-Caffey syndrome, ataxia-telangiectasia, ankylosing spondylitis, Brachmann-de Lange syndrome, and light chain deposition disease. When an isolated process occurs, there is recessive

FIGURE 9-6 ■ Tracheobronchomegaly (Mounier-Kuhn syndrome) in a 13-year-old girl with chronic cough and bronchiectasis. Computed tomography scan at the level of the trachea (**A**) and mainstem bronchi (**B**) shows air-filled sacculi (arrows) around the airway from chronic inflammation destroying the normal elastic properties of the tracheobronchial tree and its smooth muscles. (Courtesy Simon C. Kao, MD, Iowa City, IA.)

inheritance.⁹⁵ Tracheobronchomegaly also may result from severe pulmonary fibrosis with increased traction on the tracheal wall.^{96,97} As these diverticula develop, mucus retention occurs with resultant development of bronchiectasis and fibrosis. Patients eventually are unable to clear secretions, and they succumb to chronic infection and respiratory failure.

The patients are usually men in their third to fourth decades of life.⁹⁸ Fifty percent of patients with tracheobronchomegaly have no symptoms until their third decade. They usually have recurrent lower respiratory tract infections. Asymptomatic patients may be identified in that the trachea is three standard deviations larger than normal; for adults, it exceeds 3 cm.⁹⁹ Patients with tracheobronchomegaly frequently have recurrent respiratory tract infections and persistent cough. Plain chest radiography demonstrates an enlarged trachea and mainstem airways that may be ectatic. CT more clearly demonstrates changes, and tracheal dimensions for adults¹⁰⁰ and children¹⁰¹ are helpful in making the diagnosis. Bronchography may be necessary to differentiate it from acquired bronchiectasis. Bronchoscopy generally is

unrewarding because of inadequate visualization of the airway lumen as a result of multiple tracheal wall diverticula.

In general, there is no surgical role in the treatment of tracheobronchomegaly. Management of secretions helps minimize the symptoms. Stenting and T tubes^{102,103} may provide significant palliation. Tracheobronchoplasty may have a role. Recently, a successful double-lung transplantation with bilateral bronchial stents performed to treat tracheobronchomegaly was reported.^{98,104}

Laryngotracheoesophageal Cleft

Laryngotracheoesophageal cleft is a rare congenital abnormality resulting from failure of the esophagus to separate from the laryngotrachea.¹⁰⁵ Infants with this abnormality have a toneless cry and choke with feeding. On an attempt to pass a nasogastric tube, a communication with the airway is seen. A barium study or endoscopy can demonstrate the fistula. Rigid bronchoscopy is necessary to make the diagnosis and to define the extent of the lesion. One half to more than three fourths of patients survive.^{106,107} With late detection, the mortality rate is high. Patients are first treated with a gastrostomy. Then, through a cervical approach, the fistula is divided, the esophagus and larynx are repaired, and a muscle flap is placed between them to reduce likelihood of recurrence. A nasogastric stent is left in place for a time. For large defects, a combined cervical and thoracic approach may be necessary.¹⁰⁸

Tracheobronchial-Esophageal Fistula

Tracheobronchial-esophageal fistula (TEF) is the most common abnormality of the trachea, occurring in 2.4 out of 10,000 births.¹⁰⁹ The most commonly used anatomic classification system for TEF is the one proposed by Gross¹¹⁰: type A, esophageal atresia without TEF; type B, esophageal atresia with proximal TEF; type C, atresia with distal TEF; type D, atresia with both proximal and distal TEF; and type E, TEF without esophageal atresia (H-type). Type C is the most common, accounting for 87% of the anomalies, followed by type A (8%), type E (4%), type B (1%), and type D (1%). Associated congenital defects are common¹⁰⁹; cardiovascular anomalies lead the list, with concomitant occurrence in 35% of TEF cases. In approximately 20% of cases, TEF occurs as part of the VACTERL constellation of defects.

Patients present with feeding difficulties and excessive salivation. Intermittent cyanosis and tracheobronchial infections are seen as well. Diagnosis of the most common form (type C) is suspected when a large amount of air is seen in the esophagus, stomach, and small bowel. Failure of nasogastric tube passage and its position on plain radiography or contrast fluoroscopy confirm the condition. Haight is credited with the first successful pediatric TEF repair.¹¹¹ Although it was initially accomplished through left thoracotomy, Haight came to prefer right extrapleural thoracotomy for division of the fistula and esophageal anastomosis. Esophageal anastomotic leak is seen in approximately 15% of cases, but with a functioning chest tube in proximity, 95% of leaks heal spontaneously.¹¹²

Subsequent stricture formation is common, but it generally responds well to dilation. Major, life-threatening leaks occasionally occur. In this situation or in the case of so-called long-gap atresia, wherein esophageal continuity cannot be established despite a variety of elongation techniques, esophageal replacement by colonic interposition or gastric transposition may be necessary. Even in critically ill neonates with a substantial esophageal anastomotic leak, gastric pull-up has been successfully applied as an alternative to temporizing with wide drainage alone.¹¹³ Long-term outcome after surgery for TEF has been the subject of several reviews.¹¹⁴⁻¹¹⁷

For ligation of the H-type fistula, a right neck incision is made, allowing avoidance of the thoracic duct. The sternocleidomastoid muscle and carotid sheath contents are retracted laterally. The recurrent laryngeal nerve is identified and protected, and the fistula is divided and oversewn. An interposition muscle flap reduces the likelihood of recurrence. TEF recurrence has been successfully managed with a minimally invasive technique. In one pediatric series, the fistula tracts were de-epithelialized by fulgurating diathermy under endoscopic guidance with successful track obliteration by way of fibrin glue application.¹¹⁸ For the lower-lying H-type fistula not accessible through a cervical incision, thoracoscopic ligation has been successful.^{119,120} Early postoperative complications include anastomotic stricture, recurrence of fistula, and gastroesophageal reflux.

Not surprisingly, minimally invasive techniques have been increasingly applied not only to management of fistula obliteration but to esophageal reconstruction as well.¹²¹⁻¹²³ Thoracoscopic repair has been accomplished through an extrapleural approach,¹²⁴ and even long-gap esophageal atresia has been amenable to the thoracoscopic approach. The latter consists of initial thoracoscopically mediated esophageal traction followed by staged thoracoscopic creation of the esophageal anastomosis.¹²⁵ Nuances of anesthetic and intensive management of neonates undergoing thoracoscopy and laparoscopy are becoming better appreciated.^{126,127} Meticulous anesthetic management has allowed successful TEF repair in a neonate with single-ventricle physiology (unpalliated tricuspid atresia).¹²⁸ In a recent survey of 217 surgeons from 31 countries, the thoracoscopic approach to repair is used by more than 50% of the surgeons. Thoracoscopic repairs are now performed intrapleurally in 96% of cases compared with 89% performed extrapleurally with the open approach.¹²⁹

Preservation of the azygos vein, previously divided with impunity during repairs of esophageal atresia and TEF, has been advanced as desirable. The theory is that postoperative mediastinal edema may be avoided, thereby minimizing esophageal anastomotic complications.^{130,131} Clinical significance of this concept awaits further evaluation.

Bronchobiliary Fistula

Bronchobiliary fistula (Fig. 9-7) is a very rare congenital abnormality with perhaps fewer than 50 cases reported.¹³² The embryologic basis for this lesion is either that the tract represents a duplication of upper gastrointestinal

FIGURE 9-7 ■ Bronchobiliary fistula. In this child with bilious sputum and a congenital diaphragmatic defect, a fistula was found between the right mainstem bronchus and the biliary tree. (Modified from DiFiore JW, Alexander F: Congenital bronchobiliary fistula in association with right-sided congenital diaphragmatic hernia. *J Pediatr Surg* 37:1208-1209, 2002.)

tract for the distance of the gut between the laryngotracheal outgrowth and the hepatic diverticulum or that the tract results from the union of an anomalous bronchial bud with an anomalous bile duct.¹³³ It has generally been reported in infants and children, but a number of cases have been diagnosed in adulthood.¹³⁴⁻¹³⁶ The fistula track is composed of bronchial and biliary-type tissue from its origin in the airway to the liver. Patients produce green sputum and develop dyspnea and chronic cough. Infants may present with respiratory distress¹³⁷; girls are more commonly affected. The right middle lobe and right mainstem airways are most frequently involved and usually drain to the left hepatic ductal system. Associated anomalies, although not the rule, include esophageal atresia and TEF,¹³⁸ biliary atresia,¹³⁹ and right-sided diaphragmatic hernia.¹³²

Diagnosis is made by bronchoscopy, during which a catheter may be passed into the fistula for administration of contrast material and concomitant radiography.¹⁴⁰ This represents a more modern form of bronchography. Diagnosis also has been achieved with a nuclear biliary scan (^{99m}Tc-HIDA cholescintigraphy)^{141,142}; this is useful for postoperative surveillance as well. Finally, MRI for neonatal diagnosis has been reported, emphasizing the usefulness of T1-weighted gradient-echo sequences.¹⁴³

Patients with a confirmed bronchobiliary fistula are treated by ligation and division of the fistula, transecting it as close to the airway as possible. Pulmonary resection has been necessary on occasion.¹³⁵ Access is by way of transpleural or extrapleural right thoracotomy. Cholecystography is used selectively to verify biliary drainage into the duodenum.¹⁴² For those with impaired prograde biliary drainage or biliary sepsis, hepatic lobectomy (generally left-sided) or Roux-en-Y hepaticojejunostomy may be necessary.¹⁴⁴

Bronchopulmonary Foregut Malformations

Bronchopulmonary foregut malformations represent another category of congenital lung diseases. The classification includes sequestrations (intralobar and extralobar), bronchogenic cysts, and other, less common entities.

Bronchopulmonary foregut malformations are an abnormal communication between normal lung and esophagus or stomach and represent the second most frequent abnormal communication between the airway and intestinal tract, tracheoesophageal fistula being the most common. Abnormal ventral foregut budding is the embryologic basis for bronchopulmonary foregut malformations.¹⁴⁵ Right and left lower lobes are equally and most commonly affected. The fistula rarely involves the gastric fundus or mid-esophagus, almost always tracking to the lower esophagus. It is associated with extralobar sequestrations, more often on the left side. Diagnosis is usually made in the first few months of life up to 18 years of age. The most useful diagnostic test is esophagography. These malformations are associated with other anomalies, such as diaphragmatic hernia and cardiac, gastrointestinal, or vertebral anomalies. Because of chronic infection, lobectomy is usually necessary, and the fistulous communication must be divided and the esophageal defect repaired. If there is no evidence of infection, lung tissue may be preserved. Hybrid lesions refer to the overlap between congenital cystic adenomatoid malformation and sequestration.

Sequestrations

Sequestrations are lung parenchymal defects that have systematic arterial blood supply and lack continuity with the upper respiratory tract.¹⁴⁶ They are divided into intralobar and extralobar types. They are invariably located in the base of the lung, with males more frequently affected than females by a 3:1 ratio. Intralobar sequestrations (Fig. 9-8) are cystic abnormalities within the visceral pleural covering of the lung, whereas extralobar sequestrations (Rokitansky lobe; Fig. 9-9) are mass lesions that have their own separate visceral covering.¹⁴⁶ Intralobar sequestrations represent 75% of all sequestrations. As a group, intralobar sequestrations receive vascular blood supply from the thoracic aorta in 74% of cases, from the abdominal aorta in 19% of cases, from the intercostals in 3% of cases, and from multiple sources in 20% of cases. The aberrant blood supply most commonly enters the anomalous lung away from the hilum. The venous drainage of sequestrations is usually through pulmonary veins, but it may be through systemic veins. Intralobar sequestration is most frequently found within the posterior segment of the left lower lobe.

Extralobar sequestrations are rounded, smooth, soft masses that usually lie just above the dome of the diaphragm; 90% occur at the base of the left lung. The venous drainage of extralobar sequestrations occurs most frequently through the systemic circulation, to either azygos or hemiazygos systems; only 20% of cases

demonstrate venous drainage into the pulmonary veins. On microscopic examination, all lung structures are present in extralobar sequestrations, including alveoli, bronchi, and cartilage.

Intralobar and extralobar sequestrations are derived from foregut tissue and thus may possess an esophageal fistula. Intralobar sequestrations may present in utero as polyhydramnios or may become symptomatic in adolescents or young adults. Repeated bouts of pulmonary infection and hemoptysis are the most common symptoms. Intralobar sequestration is rarely associated with other congenital anomalies; extralobar sequestration is sometimes associated with other anomalies, especially congenital diaphragmatic hernias. Extralobar sequestrations may be found within either the pericardium or the diaphragm or beneath the diaphragm retroperitoneally. Malignant neoplasms have been reported within extralobar sequestrations, and a simultaneous discovery of congenital cystic adenomatoid malformation has been reported, as have other anomalies such as pericardial cysts, esophageal achalasia, and cardiac defects. In the absence of malignant disease, patients with both intralobar and extralobar sequestrations may demonstrate marked serum elevations of the tumor markers CEA and CA19-9.¹⁴⁷

CT is sensitive and specific for identification of either intralobar or extralobar sequestrations.¹⁴⁸ MRI may be helpful.¹⁴⁹ Bronchography and bronchoscopy are less likely to provide additional information. Barium esophagography may be necessary to demonstrate an esophageal communication. Angiography is seldom necessary, because noninvasive studies generally demonstrate the feeding systemic vessels.

Many lesions are discovered prenatally, and careful follow-up is recommended. If hydropic changes are noted, delivery is indicated.^{150,151} In infants, cysts that are large or cause hemodynamic compromise can be temporarily drained by needle aspiration or tube thoracostomy to allow adequate induction of anesthesia. If no infection is involved, the cyst alone, or possibly a segment, can be removed. In most cases, however, lobectomy is required. Early identification of the aberrant arterial blood supply is critical and helps avoid disastrous bleeding. Most of the arteries are less than 1 mm in diameter, but some have been reported to be as large as 2.5 mm. Atherosclerotic changes in the systemic artery may make it difficult to manipulate during surgery. A communication with the gastrointestinal tract should be thoroughly searched for at the time of surgery. Venous drainage also may be aberrant, and it should be ascertained before resection, if possible. Both intralobar and extralobar sequestrations may be amenable to resection by minimally invasive techniques. The outcomes after resection are excellent.^{152,153} The use of Amplatzer vascular plugs has been described for the control of hemoptysis in these patients.¹⁵⁴

Azygos Lobe

An azygos lobe (Fig. 9-10) is present on 0.5% of routine chest radiographs. It is found as an abnormal lobation where the azygos vein creates an additional sulcus separating two portions of the upper lobe and the azygos vein

FIGURE 9-8 ■ Intralobar pulmonary sequestration. A, Frontal chest radiograph shows consolidation of the left lower lobe. **B,** Computed tomography image of lung base shows opacification of the left posterior lower lobe. **C,** Contrast-enhanced magnetic resonance angiogram shows that a large arterial branch (*arrow*) arising from the low thoracic aorta supplies this region. (Courtesy Koji Takahashi, MD, Asahikawa Medical College, Asahikawa, Japan.)

lies within the substance of the right lung. The term *azygos lobe* is somewhat of a misnomer. This entity does not represent a true anatomic lobe because there is no separate segmental bronchus. Other regions of unusual, separate lobations may be found, particularly in the lingula or in the right and left superior segments. These abnormal lobations are not associated with any other congenital anomaly, nor do they increase the likelihood for any future pathologic or developmental abnormality. They require no treatment.

Horseshoe Lung

In this rare, recently reviewed pulmonary anomaly,¹⁵⁵ right and left lung bases are fused by common tissue extending through the posterior mediastinum anterior to the aorta but posterior to the heart and esophagus. The

clinical relevance lies in its association with recurrent pulmonary infections and pulmonary hypertension. Scimitar syndrome accompanies horseshoe lung in up to 80% of cases.^{156,157} Horseshoe lung also should be suspected in patients with the VACTERL constellation and in patients with other bronchopulmonary foregut anomalies.¹⁵⁵

Bronchogenic Cysts

Bronchogenic cysts result from abnormal budding from the perimeter of the trachea after it has differentiated from the foregut. They are the most frequent cysts of the mediastinum, accounting for approximately 60% of these lesions. Men are more frequently affected than are women. The usual location of the cysts is along the right paratracheal area, but they may also be attached to the

carina, frequently anterior to the esophagus. They may be hilar, attached to a lobar bronchus, and occasionally they are intrapulmonary. They may also be situated below the diaphragm or in the parasternal subcutaneous tissue, skin, or pericardium. The cyst's inner lining is composed of ciliated pseudostratified respiratory epithelium interspersed with goblet cells. Bronchial communication is rare.¹⁵⁸ The cysts are unilocular and usually measure 2 to 10 cm. They may contain normal bronchial elements, including cartilage and smooth muscle, which helps

differentiate a bronchogenic cyst from an enteric cyst. Noninfected cysts may contain mucus, blood, or milky material. Symptoms may relate to pulmonary artery compression and possibly paroxysmal atrial fibrillation.^{159,160} Bronchogenic cysts most commonly are an incidental finding on chest radiography, usually an air-filled cyst with or without an air-fluid level (Fig. 9-11). Serial radiographs may demonstrate rapid expansion. Intraparenchymal bronchogenic cysts more frequently present with symptoms of infection (90%) compared with mediastinal cysts (36%).¹⁶¹

The differential diagnosis of bronchogenic cyst includes lymphadenopathy, pulmonary sequestrations, teratoma, hemangioma, lipoma, hamartoma, neurogenic tumors, foregut and pericardial cysts, and lung abscesses. CT is helpful, and a low Hounsfield unit (<20) is characteristic. MRI may provide additional information. Differentiation of bronchogenic cysts from enteric cysts may be made on the basis of location: enteric cysts usually develop in the posterior mediastinum in close association with the esophagus. Also in the differential diagnosis of bronchogenic cysts, bronchopulmonary foregut malformations are usually multilocular and are more frequently associated with recurrent cough, pneumonia, and hemoptysis. Endoscopic ultrasonography may be beneficial, but endoscopic ultrasonography-directed fine-needle aspiration may be hazardous.¹⁶²

Bronchogenic cysts should be excised completely, if possible, with repair of any associated communication.¹⁶³ Needle aspiration alone is likely to result in recurrence. Mediastinoscopic unroofing has been performed and has been diagnostic. Asymptomatic cysts should be removed for diagnosis and to prevent complications associated with the natural history of these cysts, including perforation, hemorrhage, enlargement, infection, and malignant degeneration. In children, the airways are pliable and much more susceptible to life-threatening compression by an enlarging cyst.¹⁶⁴ Malignant degeneration has been reported,¹⁶⁵⁻¹⁶⁷ including an adenocarcinoma in an 8½-year-old girl.¹⁵⁸ Typically, the bronchogenic cyst can be enucleated from the mediastinum. If there is a stalk, it is ligated, and the bronchial defect is repaired. Long-term results are excellent. Video-assisted and robot-assisted removal has become increasingly popular,^{163,168} but pericystic adhesions, tracheal or bronchial communications,

FIGURE 9-9 ■ Extralobar sequestration. Extralobar sequestration is most frequently found in the lower left chest with its own pleural investment and systemic venous drainage. Computed tomography scan is beneficial in better identifying the anatomic details of the defect. (From Singh SP, Nath H: A 53-year-old man with hemoptysis. *Chest* 120:298-301, 2001.)

FIGURE 9-10 ■ Azygos lobe. **A**, An additional fissure is found in this chest radiograph. The azygos vein creates a separate division within the right upper lobe. **B**, Axial cut on computed tomography (CT) scan showing the azygos lobe. **C**, Coronal view on CT scan showing a part of the azygos vein and the azygos lobe.

FIGURE 9-11 ■ Bronchogenic cyst in a 4-month-old boy with cough. Anteroposterior (A) and lateral (B) chest radiographs show a central mediastinal mass (*white arrows*) displacing the esophagus (outlined by nasogastric tube, *black arrows*) posteriorly. C, Four contiguous axial computed tomography images of the chest show a retrotracheal and subcarinal mass with low-density contents. Excision of the mass and pathologic examination showed bronchogenic cyst. (Courtesy Simon C. Kao, MD, Iowa City, IA.)

and the possibility of malignant transformation should be considered relative indications for thoracotomy.

LUNG BUD ANOMALIES

Pulmonary Agenesis, Aplasia, and Hypoplasia

Pulmonary agenesis is the complete absence of the carina as well as the mainstem bronchus, the lung, and the pulmonary vasculature on the affected side. First described by Morgagni, fewer than 20 cases have been reported. Cardiac anomalies are usually associated when pulmonary agenesis is bilateral. Unilateral cases have cardiac anomalies in 50% and are more frequently associated with right-sided agenesis.¹⁶⁹ The sex distribution is roughly equal. Right and left agenesis is also equally distributed. There is some evidence of a chromosomal abnormality.¹⁷⁰ Left-sided pulmonary agenesis has been

reported as part of a syndrome with ipsilateral facial, radial ray, and renal agenesis in a series of three patients.¹⁷¹ In these three infants, pulmonary artery dilation caused marked bronchial compression. Associated gastroesophageal reflux exacerbated respiratory distress. Other factors associated with impaired intrauterine lung growth include intrathoracic or extrathoracic compression, diminished fetal respiratory movements, and decreased amniotic fluid volume.¹⁷² Abnormal pulmonary development can be detected on fetal ultrasound examination.¹⁷³

When the carina and bronchus are present but the vessels and parenchyma are absent, the defect is referred to as pulmonary aplasia. There is a rudimentary bronchial stump, and the carina appears to be normal. Aplasia may be present in a single lobe or in a combination of lobes. It is most frequently unilobar. The right upper and right middle lobes are the most commonly involved.

Agenesis or aplasia may be symptomatic when it is unilateral or even when a single lobe is involved. Patients may have tachypnea, dyspnea, or cyanosis. Older patients

FIGURE 9-12 ■ Right pulmonary agenesis. Frontal chest radiograph in a newborn with respiratory distress. Note complete opacification of the right hemithorax with mediastinal shift toward the same side. The patient also has esophageal atresia (nasogastric tube lodged in the dilated proximal esophageal pouch, arrow) with distal tracheoesophageal fistula (note air in the stomach). (Courtesy Simon C. Kao, MD, Iowa City, IA.)

may present with wheezing. Boys are more commonly affected than girls are. When congenital cardiac anomalies are present, cyanosis and respiratory distress are generally evident at birth.

Chest radiography shows a shift in the mediastinum toward the area of agenesis or aplasia (Fig. 9-12). Pulmonary angiography shows absence of the ipsilateral pulmonary artery. Bronchoscopy may be helpful to evaluate bronchial stump presence, length, and character in patients with aplasia. CT and esophagography are helpful elements of the evaluation to differentiate agenesis or aplasia from sequestration and atelectasis.

Bilateral agenesis is incompatible with life. Survival periods of up to 6 years in right-sided lesions and up to 16 years in left-sided lesions have been reported.¹⁷⁴ Of those surviving the neonatal period, 30% die within the first year and 50% succumb within the first 5 years of life.¹⁷⁵

In pulmonary hypoplasia, the bronchus and the bronchial tissue are poorly formed, and there is a reduced number of alveoli. Lung weight is at least one standard deviation below the mean.¹⁷⁶ Most cases of hypoplasia are the result of another defect that prevents normal lung development, such as a diaphragmatic hernia, chest wall defect, bone dysplasia, or even muscular dystrophy. Primary pulmonary hypoplasia is rare and is frequently associated with Down syndrome.¹⁷⁷ It is often fatal and is the result of hypertrophy of the pulmonary artery smooth muscle and resultant pulmonary artery hypertension. Associated congenital abnormalities also reduce the life expectancy of these patients.

In pulmonary aplasia, removal of the rudimentary stump may be necessary if it is recurrently infected. There is no specific surgical therapy for pulmonary hypoplasia, except to treat the cardiac anomalies or to ameliorate the chest wall anomalies. The severity of the pulmonary artery hypertrophy may result in persistent fetal circulation. At delivery, the affected infant may be hypoxemic, acidotic, and hypercarbic. Such patients are treated with sedation, paralysis, high-frequency ventilation, vasodilators, respiratory alkalosis, and, if necessary, ECMO. Survival has improved with ECMO.¹⁷⁸⁻¹⁸⁰ Another means to treat these patients is with high-frequency oscillatory ventilation.¹⁸¹ One half of the infants with congenital diaphragmatic hernias require ECMO, and 70% of those patients survive. In patients with a congenital diaphragmatic hernia, it is unnecessary to resect the underdeveloped lung at the time of diaphragmatic repair. There should be no attempt to aggressively inflate the lung. Bilateral lung transplantation has been performed in extreme circumstances.¹⁸² Antenatal surgical therapy has been directed at relief of lung compression, but efficacy is equivocal.¹⁸¹ Surgical options have recently been reviewed,¹⁸³⁻¹⁸⁵ although the absence of large randomized trials precludes robust quantification of risks and benefits of antenatal surgery vis-à-vis postnatal therapy. A review of the literature shows 53 reported cases of cardiac surgery being performed in patients with unilateral pulmonary agenesis or atresia with a reported 7.7% mortality.¹⁸⁶

Congenital Lobar Emphysema

Congenital lobar emphysema represents 50% of all congenital lung anomalies. It is a postnatal overdistention of histologically normal and mature lung parenchyma resulting from a disorder of the bronchial patency, of either internal or external causes.¹⁸⁷ It is the result of obstruction of a lobar bronchus, usually an upper airway, resulting in overexpansion of alveolar airspaces but lacking parenchymal destruction, in contradistinction to the adult form. The vasculature to the affected lobe is normal. A subtype, congenital segmental emphysema, has recently been described.¹⁸⁸

Expanded lung frequently compresses adjacent lung and, in some cases, shifts the mediastinum away from the emphysematous lobe. Other descriptive terms include infantile lobar emphysema, congenital segmental bronchomalacia, congenital lobar overinflation, and emphysema of infancy or childhood. A cartilaginous defect obstructs the lobar bronchus in 25% of cases.¹⁸⁹⁻¹⁹¹ Other potential causes of intrinsic obstruction include mucus plugging and intraluminal granulation tissue. Extrinsic obstruction may result from cardiac or vascular anomalies such as tetralogy of Fallot, pulmonary stenosis, anomalies of pulmonary venous return, adenopathy, mediastinal tumors, and bronchogenic or enteric duplication cysts.¹⁹² In more than one half of the cases, there is no identifiable causative factor.¹⁹³

Patients with congenital lobar emphysema are symptomatic at birth. Within several days, they can develop wheezing, dyspnea, or cough.⁵⁴ The left upper lobe is most frequently involved, followed by the right upper

lobe, then the right middle lobe, and finally the lower lobes.¹⁹⁴ When it develops bilaterally, it is usually the left upper lobe and the right middle lobe that are affected. There is a 3:1 male-to-female ratio of involvement. Of those affected, 80% are symptomatic by 6 months of age. Fourteen percent of patients have an associated cardiac malformation. Rib and thoracic cage abnormalities also are common. If congenital lobar emphysema is symptomatic but left untreated, the mortality is 50% within the first week, and an additional 30% to 40% of patients will die during the next month.

In the newborn with severe respiratory distress, a chest radiograph usually suffices for diagnosis (Fig. 9-13A). The combination of an enlarged, hyperlucent lobe with fairly normal vasculature coupled with compression of

adjacent lung tissue and contralateral mediastinal deviation is diagnostic. For mild to moderate symptoms, a CT scan (see Fig. 9-13B) may be necessary to rule out mediastinal masses or vascular anomalies. In older children, bronchoscopy can be helpful to assess for mucus plugs or foreign bodies. Bronchography is unlikely to be helpful and is rarely used now. The ventilation-perfusion scan has yielded useful information in some cases.¹⁹⁵ Respiratory distress in the newborn must be differentiated from other lung abnormalities, such as pneumothorax, congenital diaphragmatic hernia, parenchymal lung cysts with a ball-valve mechanism, cystic adenomatoid malformation, and extralobar sequestration.

Acquired lobar emphysema is yet a different disease entity, a complication of respiratory distress syndrome and long-term mechanical ventilation and usually develops in the right upper lobe. In acquired childhood emphysema, lung scans demonstrate low flow to the affected lung, in contrast to normal flow in the congenital form.¹⁹⁶ For the congenital form, echocardiography and additional tests (e.g., magnetic resonance angiography) may be required to evaluate for associated cardiac or vascular anomalies. There is no surgical indication for asymptomatic or mildly symptomatic patients. Pulmonary function is likely to remain stable. One half of the patients will normalize during infancy. For patients who are symptomatic, all emphysematous tissue should be resected. Lobectomy is frequently required. Segmental resection when possible is also appropriate management.¹⁸⁷ Operative mortality is as high as 7% in some series. The greatest risk appears to be at the time of anesthesia induction. Selective intubation has been used to prevent overinflation of the emphysematous lobe, with resulting cardiovascular collapse.¹⁹⁷ High-frequency ventilation also has been used to prevent mediastinal shift and hemodynamic compromise.¹⁹⁸ Needle aspiration has been performed as necessary.¹⁹⁹ In addition, flexible fiberoptic bronchoscopy has been used in the neonate to decompress an emphysematous lobe.²⁰⁰ The surgeon should be prepared for immediate thoracotomy soon after induction. Once the chest is open, the emphysematous lobe may spontaneously project out of the chest. Typically, it remains inflated even after the lobe has been removed. The hilar anatomy is usually normal, and the goal should be to resect all of the emphysematous tissue, preserving the adjacent normal lung. Lung function is compromised after resection,^{193,201} but the child's development is normal.²⁰² Long-term follow-up has been reported.²⁰³ In contrast to patients with congenital lobar emphysema, those with acquired lobar emphysema progress to further respiratory difficulties after lung resection.²⁰⁴ Balloon dilation of the airway stenosis has been used successfully.²⁰⁵

Management of coexisting congenital lobar emphysema and congenital heart disease has been described in detail.²⁰⁶ Presence or absence of pulmonary hypertension is a key factor in the development of an operative strategy. On occasion, the emphysema may be caused by vascular compression of a bronchus, such as in the case of a large ductus arteriosus. The emphysematous changes may resolve after surgical correction of the vascular anomaly.

FIGURE 9-13 ■ Congenital lobar emphysema. **A**, Chest radiograph of a 1-month-old boy shows hyperlucency in the right lower lung field. **B**, Computed tomography image of the lungs just below the carinal bifurcation shows right middle lobe emphysema with paucity of blood vessels and decreased attenuation. (Courtesy Simon C. Kao, MD, Iowa City, IA.)

Congenital Parenchymal Cysts

Congenital parenchymal cysts are rare and may develop as a unilocular entity within the parenchyma, most commonly in the left lower lobe. An aberrant systemic artery often supplies the cyst region. Such cysts are lined with mucus-secreting pseudostratified columnar epithelium. The cyst usually communicates with a bronchus. This condition may represent a variant of cystic adenomatoid malformation. It may also result from entrapped lung blood, with subsequent air trapping after the blood has been resorbed. Affected infants show symptoms ranging from a chronic cough to frank sepsis. Congenital parenchymal cysts are frequently associated with other anomalies. This disease category includes intraparenchymal bronchogenic cysts.²⁰⁷ Parenchymal cysts are associated with subtype B Niemann-Pick disease.²⁰⁸

Respiratory distress is common within the first few days of life, and the cyst often becomes infected by the first few weeks of age. Air trapping may shift the mediastinum.

It may be difficult to differentiate a cyst from an intraparenchymal abscess. The presence of a systemic artery feeding the cyst is diagnostic. Failure of the cyst to completely collapse with tube drainage also is helpful in making the diagnosis. Other anomalies that appear similar include congenital diaphragmatic hernia and postpneumonic staphylococcal pneumatoceles.

Once discovered, congenital parenchymal cysts can be observed unless they become infected, expand, or are otherwise symptomatic. If present for more than a year, they are unlikely to resolve. As noted before, malignant transformation of a pulmonary cyst is a concern.²⁰⁹ For infected cysts, preliminary antibiotic treatment is followed by resection once sepsis subsides. Lobectomy is usually necessary, although cyst resection can suffice, for example, by right S3 segmentectomy.²⁰⁷ Pneumonectomy occasionally may be necessary for definitive treatment. Management of congenital parenchymal lung cysts has been grouped with that of congenital cystic adenomatoid malformation, congenital lobar emphysema, and sequestrations to compare and contrast the fine points of each entity.²¹⁰ Perioperatively, a combination of one-lung high-frequency ventilation and low-rate intermittent mandatory ventilation has been described for the management of the symptomatic neonatal lung cyst.²¹¹

Congenital Cystic Adenomatoid Malformation

Congenital cystic adenomatoid malformation (CCAM) was first described in 1949.²¹² Also referred to as congenital pulmonary airway malformation (CPAM),²¹³ CCAM is a mass consisting of excessive proliferation of bronchi but without normal alveolar development. Composed of cartilage, smooth muscle, and bronchial glands containing columnar and cuboidal epithelial cells, CCAM represents 25% of all congenital lung anomalies (second only to congenital lobar emphysema). There is normal vascular development, and the affected area communicates with the normal airway. Usually only one lobe is affected, and that lobe generally has a solitary lesion.

The abnormality may be identified in the fetus whose mother develops polyhydramnios by the 23rd week of gestation. Up to one third of those identified in utero resolve before birth.¹⁸⁹⁻¹⁹¹ In most cases, CCAM manifests as neonatal acute respiratory distress with or without associated lung infection. CCAM must be differentiated from congenital diaphragmatic hernia because both entities show multiple air-fluid levels within the affected hemithorax. The initial chest radiograph shows a solid mass. Over time, the fetal fluid is resorbed and the cysts become filled with air (Fig. 9-14). A CT scan may be helpful in achieving a diagnosis. The most commonly associated anomaly is pectus excavatum, and cardiac and pulmonary vessel malformations can be present as well. The Stocker classification assists in treatment planning, categorizing presentations into types I, II and III.²¹⁴ Type I lesions are large, widely spaced, and irregular cystic structures that exceed 1 cm. Affected patients usually reach term but occasionally are stillborn. It is rare to have polyhydramnios or other anomalies associated with a

FIGURE 9-14 ■ Cystic adenomatoid malformation. **A**, Chest radiograph of a newborn with ill-defined lesions in the mid-left lung field. **B**, Computed tomography image of the chest shows multicystic lesions in the same region. Excision and histologic examination showed cystic adenomatoid malformation. (Courtesy Simon C. Kao, MD, Iowa City, IA.)

type I lesion. Of these patients, 75% have mediastinal shifting with some associated cyanosis and grunting. The prognosis is generally good. One half of the patients develop pneumonia in infancy and early childhood. In type II CCAM (40% of cases), the cysts are smaller than 1 cm and have an appearance of dilated bronchioles. The patients are more frequently premature or stillborn. Mediastinal shift is less often seen, and there appears to be more bronchiolar proliferation. Type III lesions are very small cysts, less than 0.5 cm. They represent 10% of all cases. The mass is much firmer, appearing to surround the entire affected lobe, most often the lower lobe. Prognosis is very poor, and patients usually expire within a few hours of birth. The new Stocker pathologic classification of CCAMs has five subtypes based on origin.²¹³

Asymptomatic CCAM patients may be observed for the first 4 to 6 months. Repeated CT at 6 months is performed to assess for CCAM enlargement or malignant degeneration (a consideration but a poorly defined phenomenon in this condition). Delayed intervention allows the child to mature, reducing the operative morbidity. Lesion shrinkage or disappearance, compensatory hypertrophy of normal lung, and unlikely occurrence of later malignant neoplasia all support a conservative approach in asymptomatic patients.²¹⁵ Only approximately 10% of untreated asymptomatic lesions eventually become clinically significant.²¹⁶ Any lesion that decreases in size but has not completely regressed should be observed until it has completely resolved. Many surgeons still favor resection of cystic lung lesions in asymptomatic neonates, citing persistent risk of infection or malignant transformation.^{217,218} Of the total number of primary pulmonary rhabdomyosarcomas and malignant mesenchymomas of lung reported in children, approximately 50% have antecedent lung cysts.²⁰⁹ Symptomatic lesions after birth certainly should be resected, and lobectomy has been considered the standard operation. Remaining unaffected lung tissue should be preserved. There is evidence that segmentectomy and wedge resection, when feasible, are just as efficacious as lobectomy, with the obvious advantage of maximizing pulmonary reserve, provided prolonged pulmonary air leaks are avoided.²¹⁹ By extension, with ipsilateral multilobar involvement, segmentectomies allow avoidance of pneumonectomy. After *complete* CCAM resection, prognosis is generally excellent.

Antenatal diagnosis suggests the possibility of in utero surgical therapy, but efficacy remains controversial. Crombleholme proposed using the ratio of lesion mass to the head circumference, the CCAM volume ratio (CVR), for follow-up and/or to predict fetal demise.²²⁰ For most cases, normal delivery with postnatal evaluation is sufficient. Only few CCAMs cause fetal problems, with fetal hydrops being the best predictor of death. When the CVR is higher than 1.6, the risk for hydrops ranges between 15% and 75%.²²⁰ Successful serial cyst aspiration has been demonstrated in fetal CCAM.²²¹ Other fetal procedures to be considered include placement of a thoracoamniotic shunt, prenatal steroids, open resection of large lesions, or EXIT.^{213,222} However, in one study, only 8 of 20 infants who had a prenatal diagnosis of CCAM were symptomatic in the neonatal period.²²³ Minimally

invasive techniques and parenchyma-sparing techniques are increasingly used, with good success for the management of these lesions in infancy and early childhood.²²⁴

Infantile Pulmonary Emphysema

Infantile pulmonary emphysema is uncommon, accounting for approximately 2% of congenital anomalies. Its morphologic spectrum has been described in detail in a series of 33 cases accessioned to the Armed Forces Institute of Pathology in Washington, DC, during an approximate 30-year period.²²⁵ An entity different from congenital lobar emphysema, infantile pulmonary emphysema does appear most prominently in the upper lobes and is multilobar in approximately 20% of cases. Associated anomalies are common. The condition presents as gas surrounding the bronchovascular structures and may evolve to pneumomediastinum or pneumothorax. It occurs in approximately 20% of patients with respiratory distress syndrome and 40% of patients who require positive end-expiratory pressure. Infantile pulmonary emphysema can appear as diffuse multicystic abnormalities within all lobes.²²⁶ It must be differentiated from CCAM and congenital diaphragmatic hernia. Once the diagnosis is made, less than 2% of patients require surgical resection; most improve with supportive measures alone. Atelectasis, ventilator dependence, and recurrent or persistent infections are indications for surgery. Thoracentesis or thoracostomy is necessary to treat pneumothorax and respiratory embarrassment. Resection of affected tissues with preservation of relatively healthy parenchyma is the objective of surgical intervention.

Polyalveolar Lobe

Polyalveolar lobe is a significant increase in the number of alveoli compared with the bronchi. It was first described in 1970 and was thought to be congenital lobar emphysema.²²⁷ Polyalveolar lobe is differentiated from lobar emphysema in that there is little trapped air and no true emphysematous changes. Radiographic translucency in this condition is the result of a reduction in vasculature to amount of lung, unlike congenital lobar emphysema.^{227,228} There appears to be retention of fetal lung liquid in these patients, an occurrence not primarily associated with congenital lobar emphysema.²²⁹ However, polyalveolar lobe may at times give rise to congenital lobar emphysema.¹⁹³ There may also be a relationship between polyalveolar lobe and type II CCAM²³⁰ and with infantile pulmonary emphysema.²²⁵ In older children, bronchoscopy should be performed to differentiate obstructive emphysema from foreign bodies or bronchial obstructive inflammation. Diagnosis is usually made by high-resolution CT. Resection is performed as necessary for symptomatic patients.

Pulmonary Lymphangiectasia

Pulmonary lymphangiectasia (Fig. 9-15) was first described by Virchow as diffuse cystic lymphatic duct dilation in infancy.²³¹ There are primary and secondary forms. The primary form involves dilated lymphatic

FIGURE 9-15 ■ Pulmonary lymphangiectasia. **A**, The chest radiograph demonstrates the bilateral “soap bubble” appearance of lymphangiectasia. **B**, Gross findings at surgery demonstrated the cystic nature of the disease.

channels within the lung, and the secondary form results from pulmonary venous obstruction. Both forms are symptomatic in neonates, with respiratory distress and cyanosis. One half of these patients have associated cardiac anomalies, usually involving venous return. Their chest radiographs demonstrate a “soap bubble” appearance with ground-glass opacification. CT is more specific in making the diagnosis, but even with current techniques, it may be radiographically difficult to distinguish pulmonary lymphangiectasia from congenital lobar emphysema.²³² Lymphoscintigraphy is a helpful adjunct to CT in distinguishing lymphangiectasia from lobar emphysema.²³³ Almost exclusively diagnosed in infants, it has been seen in adults, with histologic verification after thoracoscopic pulmonary resection.²³⁴

Lymphatic obstruction may be secondary to venous obstruction. Congenital chylothorax may result. Thus, venous impairment may indirectly produce nonimmune hydrops fetalis and the concept of a congenital pulmonary lymphangiectasia–congenital chylothorax–hydrops fetalis continuum has been proposed.²³³ Patients with pulmonary lymphangiectasia may also have extrapulmonary organ involvement, especially in the alimentary canal and solid organs of the abdomen. Prognosis correlates best with the degree of pulmonary involvement, and outcome is worse when pulmonary involvement is extensive.²³⁵ Prognosis is particularly poor if pulmonary lymphangiectasia is present bilaterally. Survival beyond infancy is unusual, but overall outcome may be better than once believed.^{236–238}

To effect survival, immediate postnatal ventilator support and pleural drainage are almost always required. Progress in neonatal intensive care has improved the outlook for these severely ill infants. Surviving patients have a course similar to that of others with major chronic lung disease. Home oxygen therapy, symptomatic treatment of wheezing and cough, and intermittent pleural drainage are generally necessary.²³⁹ Successful pleurodesis using autologous blood instillation and Betadine have been reported.²⁴⁰ Ethiodized oil (Lipiodol, Roissy–Charles de Gaulle Cedex, France) is an oil-based contrast agent used for lymphangiography and can be both diagnostic and therapeutic. Because of its high viscosity, Lipiodol results in mechanical occlusion of the lymphatic vessels.²⁴¹

Whereas most cases of pulmonary lymphangiectasia occur sporadically, the condition has been seen in siblings.²⁴² Candidate gene mutations include vascular endothelial growth factor receptor 3 (VEGFR3)²⁴³ and *FOXC2* in families with Milroy and lymphedema-distichiasis syndromes, respectively. According to the same research team, a correlating animal model of fatal chylothorax may be that of α_9 -deficient mice. Postmortem examination of one infant who died of pulmonary lymphangiectasis revealed marked upregulation of endothelial nitric oxide synthase in that disorder.²⁴⁴ From an immunohistochemical standpoint, key antibody markers useful in confirming the diagnosis of lymphangiectasis include CD31, CD34, desmin, smooth muscle actin, and D2-40.²⁴⁵

VASCULAR ABNORMALITIES

Unilateral Absence of a Main Pulmonary Artery

Absence of a main pulmonary artery is exceedingly rare and is commonly associated with other cardiac anomalies. It was first described by Frentzel in 1868.²⁴⁶ The pulmonary vein to the affected lung is normal, but the arterial supply derives from a systemic artery that is usually adjacent to the trachea. Patients develop recurrent respiratory infections and dyspnea in later childhood. Hemoptysis is the most serious complication and may be associated with bronchiectasis. Pulmonary infection warrants surgical resection. Of the 352 cases reported in the literature, 237 were associated with congenital cardiac defects.²⁴⁶ The presence of good intraparenchymal pulmonary arteries warrants surgically establishing a connection to the main pulmonary artery or the creation of a systemic to pulmonary shunt. Pulmonary hypertension is a severe complication of this disease process.²⁴⁶

Idiopathic, Hyperlucent Lung Syndrome (Swyer-James or Macleod Syndrome)

Hyperlucent lung syndrome is defined as a small or normal-sized lung with few pulmonary vessels and associated air trapping. A very rare anomaly with a prevalence of 0.01% in routine chest radiographs, it was first

described by Swyer and James²⁴⁷ and later by Macleod.²⁴⁸ It is thought to result from chronic childhood lower respiratory tract infections, potentially caused by bronchiolitis obliterans, that lead to pulmonary vascular changes and bronchiectasis.

Radiographically this syndrome is characterized by hyperlucency of a lobe or the entire lung with decreased vascular markings with no bronchial obstruction. Areas of bronchiectasis may be present. Patients are usually asymptomatic. A small or normal-sized lobe that is hyperlucent is incidentally discovered by chest radiography. Infants with the condition may have a mildly productive cough or dyspnea. CT and bronchoscopy are helpful in evaluating these patients. Agenesis or hypoplasia of the pulmonary artery can be associated with hyperlucent lung, but air trapping is absent, an important finding in this syndrome. A dynamic inspiratory and expiratory CT scan is performed to assess for trapping. The pulmonary vessels are markedly diminished. Hyperlucent lung usually requires no treatment, although surgical resection as a means of lung volume reduction has been reported.²⁴⁹

Pulmonary Artery Sling

Pulmonary artery sling relates to an anomalous origin of the left pulmonary artery. It arises from the right pulmonary artery anteriorly and then passes over the right mainstem bronchus behind the trachea and in front of the esophagus. Prevalence is reported as 59 per million school-age children based on a large two-dimensional echocardiographic study. It may be associated with tracheal stenosis secondary to complete cartilage tracheal rings. Symptoms include respiratory distress, choking, cyanosis, and stridor. The chest radiograph demonstrates hyperinflation. Bronchoscopy should be performed to rule out complete tracheal rings.²⁵⁰ Esophagography and CT (Fig. 9-16) may help assess the anatomy.

To correct the anomaly, the pulmonary artery is transected through a median sternotomy with the use of cardiopulmonary bypass. The left pulmonary artery is transected and reanastomosed to the main pulmonary

FIGURE 9-16 ■ Pulmonary sling (aberrant left pulmonary artery). Four contiguous enhanced computed tomography images at the level of the aortopulmonary window show that the left pulmonary artery (arrow) arises from the right pulmonary artery. (Courtesy Koji Takahashi, MD, Asahikawa Medical College, Asahikawa, Japan.)

artery anterior to the trachea. If tracheal stenosis is present, it may be treated at the same time. Others have reported an alternative procedure in which the trachea is divided and the left pulmonary artery is moved anterior to the trachea before the trachea repair is performed.^{251,252} Backer and Holinger²⁵⁰ reported on 34 patients who underwent repair of pulmonary artery sling through a median sternotomy with no early mortality and four late deaths. Complete tracheal rings were addressed at the same index operation. Slide tracheoplasty is the current procedure of choice for long-segment tracheal stenosis, and resection with reanastomosis is preferred for short-segment stenosis.

Isolated Pulmonary Artery Aneurysm

Pulmonary artery aneurysm (Fig. 9-17) is a rare vascular anomaly first described in 1947 by Deterling and Clagett.²⁵³ Approximately 40% to 50% of isolated pulmonary artery aneurysms are congenital, and a familial pattern has been described.²⁵⁴ Sporadic causes include penetrating trauma, prior chest tube placement, and pulmonary artery catheter-related injury. Pulmonary artery aneurysms have also been associated with infection from syphilis, tuberculosis (Rasmussen aneurysms), or, more frequently, fungus.²⁵⁵ Isolated aneurysms may also be associated with pulmonary arterial vasculitis in giant cell arteritis or Behçet syndrome. Behçet syndrome, which usually presents with oral and genital ulcers and uveitis, is a widespread vasculitis in which 5% of patients have pulmonary artery aneurysms from inflammatory destruction of the pulmonary arterial vasa vasorum. Hughes-Stovin syndrome may represent a subset of Behçet syndrome without the oral or genital ulcers but with associated peripheral venous thrombosis.

Pulmonary artery aneurysms may occur in a main pulmonary artery or in a lobar or segmental artery and are

FIGURE 9-17 ■ Isolated pulmonary artery aneurysm.

either fusiform or saccular. Patients with isolated pulmonary artery aneurysms are usually asymptomatic, with lesions only recognized as a mass on chest radiography. Further evaluation is obtained with high-resolution CT, magnetic resonance angiography, or, classically, pulmonary artery angiography. Transesophageal echocardiography may be helpful for assessment of any associated thrombosis.

Rupture of a pulmonary artery aneurysm generally results in overwhelming hemoptysis or hemothorax, and aneurysms that are enlarging or symptomatic should be treated.²⁵⁶ If the lesions are fairly peripheral, embolization may be performed.²⁵⁷ In patients who have Behçet syndrome or Hughes-Stovin syndrome, immunosuppressive agents may be helpful in reducing the associated symptoms. Anticoagulation is used cautiously. Resection of the lung, primary resection of the pulmonary artery with reanastomosis, patch repair, and graft replacement have been performed.²⁵⁸ In the case of vasculitis, there is a 25% recurrence rate,²⁵⁹ which may be mitigated by perioperative medical treatment with steroids and immunosuppressive medications.

Dysphagia Lusoria

Dysphagia secondary to compression of the esophagus by a vascular structure is known as dysphagia lusoria. The most common vascular abnormality causing this is an aberrant right subclavian artery²⁶⁰ (Fig. 9-18). Management depends on defining the vascular abnormality causing the compression and correcting it surgically. With an aberrant right subclavian artery, it is often reimplanted into the carotid artery.

Pulmonary Vein Abnormalities

Congenital anomalies of the pulmonary veins, which cause their dilation, include scimitar syndrome, partial

anomalous pulmonary venous return (PAPVR), pseudo-scimitar syndrome, and pulmonary vein varix. The number of pulmonary veins draining into the left atrium can vary from one to five.²⁶¹ The presence of a single pulmonary vein (Fig. 9-19) either on the left or the right side has an incidence of 23.9%.^{261,262} An additional right middle pulmonary vein occurs in 1.6% of cases.²⁶¹ These abnormalities have implications for lung resection and lung transplantation.

Pulmonary Varix

Pulmonary varix is an aneurysmal dilation of a pulmonary vein. It may be seen in any area of the lung, and it is a very rare anomaly; as of 1988, only 71 cases had been reported.²⁶³ It is believed that varying combinations of two processes may be important for the development of a varix: pulmonary venous hypertension and inflammatory changes in the area of the affected pulmonary vein. Congenital pulmonary vein varices result from dilation of embryologic venous drainage channels.²⁶⁴ It has been described with bronchiectasis, tuberculosis, mitral valve disease, and congenital cardiac anomalies. Single lesions are usually asymptomatic; when symptoms are present, they are generally attributable to the associated cardiopulmonary condition. The age range at presentation is between 7 and 82 years, and most symptomatic patients present in their fourth to seventh decades of life. There is an equal gender distribution.

Pulmonary varix has been described as a surprise discovery at cervical mediastinoscopy.²⁶⁵ It may also present with symptoms of cerebral embolism or hemoptysis from spontaneous rupture into a bronchus. In patients who have a varix from mitral valve disease, it is more frequently found in the right lung. When a pulmonary varix is identified incidentally, an evaluation for cardiac disease should ensue. On pulmonary angiography, a Müller maneuver (inspiratory effort against a closed glottis after

FIGURE 9-18 ■ **A**, Esophagogram showing posterior indentation of the esophagus secondary to vascular compression. **B**, Three-dimensional magnetic resonance imaging reconstruction revealing an aberrant right subclavian artery in the same patient.

expiration) increases the size of the varix, whereas a Valsalva maneuver decreases its size. CT or dynamic CT may be helpful. Three anatomic forms are recognized: saccular, tortuous, and confluent. The confluent form designates a dilation of the confluence of veins and is

FIGURE 9-19 ■ Axial computed tomography scan showing a single pulmonary vein trunk on the left side draining into the left atrium.

more frequently associated with mitral and left-sided heart disease.²⁶³ Patients with asymptomatic pulmonary varices and without cardiac or infectious disease may be observed with a good prognosis.²⁶⁶ If a cardiac anomaly is present, it should be repaired; this will frequently result in regression of the varix. Hemoptysis associated with noncardiac cases warrant resection.²⁶⁴

Pulmonary Arteriovenous Malformations

As the name implies, pulmonary arteriovenous malformations involve a direct connection between branches of a pulmonary artery and vein. They may be acquired lesions from trauma, schistosomiasis, cancer, or actinomycosis and have been associated with the physiologic and hormonal changes of pregnancy. One third of patients have hereditary hemorrhagic telangiectasia (HHT, also known as Osler-Weber-Rendu syndrome). Sixty-five percent of patients with pulmonary arteriovenous malformations have single lesions, of which more than 50% are less than 1 cm in size, and lesions are rarely larger than 5 cm. They are frequently subpleural in location. Patients may present with hemoptysis, chest pain, epistaxis, and palpitations; complications also include cerebral thrombosis, brain abscesses, and pneumothorax. Children are more likely to have diffuse lesions associated with cyanosis and congestive failure.

The chest radiograph may demonstrate a noncalcified mass, and dynamic CT and pulmonary angiography may be helpful in achieving a diagnosis (Fig. 9-20). Patients

FIGURE 9-20 ■ Pulmonary arteriovenous malformation. Selective left pulmonary arteriography and coil embolization in a 14-year-old girl. **A**, Left pulmonary arteriogram shows a tangle of vessels (asterisk) at left lung base with arterial supply (white arrow) from a basal branch of left lower lobe artery and early pulmonary venous opacification (black arrow). **B**, After embolization of coils (arrow) by superselective catheterization, the malformation is occluded. (Courtesy Simon C. Kao, MD, Iowa City, IA.)

with suggestive radiographic findings should be evaluated for recurrent epistaxis, skin lesions, or hematuria (HHT), as well as a family history of similar complaints. HHT is a rare autosomal dominant abnormality that is associated with mucocutaneous and visceral telangiectasias. Between 7% and 15% of patients with HHT have pulmonary

arteriovenous malformations; when pulmonary arteriovenous malformations are present, patients have an increased likelihood for complications such as hemoptysis, polycythemia, epistaxis, cerebral bleeding, and brain abscesses.²⁶⁷ Contrast-enhanced transthoracic echocardiography has been helpful in assessing patients with

FIGURE 9-21 ■ Scimitar syndrome. **A**, Frontal chest radiograph shows a curvilinear bandlike shadow (*arrow*) parallel to the right-sided heart border with broadening toward the right hemidiaphragm. **B**, Digital subtraction angiogram shows anomalous right pulmonary venous drainage (*arrows*) to the junction between the hepatic venous confluence and the inferior vena cava. **C**, Coronal view computed tomography scan of a different patient with scimitar syndrome showing the right vein draining into the right atrium. **D**, Abdominal angiography in the same patient showing arterial blood supply from an accessory blood vessel arising from the abdominal aorta. **E**, Artery occluded using an intra-arterial device. (**A** and **B**, Courtesy Koji Takahashi, MD, Asahikawa Medical College, Asahikawa, Japan.)

pulmonary arteriovenous malformations, with a sensitivity of 94%.

If the patient has HHT or is symptomatic, if the lesion is large, or if the diagnosis is questionable, surgical resection may be necessary. In the case of HHT, one half of patients left untreated progress to brain abscess and stroke.^{268,269} If the lesion is resected, proximal vessel control is advisable. When telangiectasias are found, only symptomatic or enlarging lesions should be treated. When telangiectasias are present on the lung surface, it is unnecessary to resect them unless they are unusually large.

One other congenital anomaly of note is scimitar syndrome (hypogenetic lung syndrome)²⁷⁰ (Fig. 9-21). In this condition, the venous drainage from either part of the right lung or the entire right lung enters the inferior vena cava rather than the left atrium. Right lung arterial supply also may be anomalous with associated pulmonary sequestration or pulmonary hypertension. Left-to-right shunting may be so significant, akin to an atrial septal defect, that surgical repair may be necessary. Surgical options have recently been reviewed.²⁷¹

CONCLUSION

This chapter reviews the wide range of congenital lung diseases. Abnormalities may involve the tracheobronchial tree, lung parenchyma, or pulmonary vasculature. Defects may be so severe as to result in stillbirth or profound neonatal respiratory distress. Other manifestations assume a more insidious course. Knowledge of pulmonary embryology and historical contributions relating to these disorders allows a logical diagnostic and therapeutic approach in most cases. Advances in technology, neonatal surgery, and antenatal diagnosis and treatment have led to a markedly improved outlook for patients with congenital lung diseases.

BENIGN LESIONS OF THE LUNG

Doraid Jarrar • Benjamin Wei • Ayesha S. Bryant • Robert J. Cerfolio

CHAPTER OUTLINE

DEFINITION AND INCIDENCE

EVALUATION FOR AN INDETERMINATE PULMONARY NODULE

HAMARTOMA

MUCOUS GLAND ADENOMA

INFECTIOUS GRANULOMATOSIS

INTRAPULMONARY FIBROUS TUMOR

BENIGN ENDOBRONCHIAL FIBROUS HISTIOCYTOMA

GRANULAR CELL TUMOR

INFLAMMATORY PSEUDOTUMOR

PAPILLOMAS

NODULAR AMYLOID LESION

CHONDROMA

MYOEPITHELIOMA

MUCINOUS CYSTADENOMA

ALVEOLAR ADENOMA

LEIOMYOMA

LYMPHANGIOLEIOMYOMATOSIS

CLEAR CELL TUMOR (SUGAR TUMOR)

PRIMARY PULMONARY THYMOMA

CONCLUSION

DEFINITION AND INCIDENCE

Benign lesions of the lung are rare. A benign lung nodule is difficult to define and classify because some lesions that are called *benign* have malignant properties. However, the best definition of a benign lesion is one in the pulmonary parenchyma that does not metastasize and does not penetrate through surrounding tissue planes. When it is completely resected, a benign tumor should not recur.¹

Benign lung tumors can be classified pathologically, but a clinically useful classification would combine location (i.e., endobronchial or parenchymal) and information about whether the lesions are single or multiple. Benign lung tumors can also be classified by their presumed origin. Those classifications include unknown (hamartoma, clear cell, teratoma), epithelial (papilloma, polyps), mesodermal (fibroma, lipoma, leiomyoma, chondroma, granular cell tumor, sclerosing hemangioma), and other (myofibroblastic tumor, xanthoma, amyloid, mucosa-associated lymphoid tumor).

The controversy arises because some tumors are often labeled *benign*, such as pulmonary blastomas, but have the potential to exhibit malignant properties, and thus clear-cut boundaries between malignant and benign often are blurred. Benign tumors of the lung can arise from all of the various cell types that are present in the lung. [Box 10-1](#) lists the most common benign tumors based on their cells of origin.

Most times, benign nodules are resected because of the inability to differentiate them from a malignant process. For this reason, a benign lesion is identified after resection. The typical evaluation of a patient with an indeterminate pulmonary nodule is described next.

EVALUATION FOR AN INDETERMINATE PULMONARY NODULE

The single most important test for a patient who arrives at the office with an indeterminate pulmonary nodule is the review of old chest radiographs and computed tomographic (CT) scans. The radiograph should be interpreted in the context of the patient's medical history. Important factors include a history of a previous solid organ cancer and history of smoking. The physical examination is typically unremarkable, without any cervical lymphadenopathy. If the nodule is new or if the patient did not have a previous chest radiograph, chest computed tomography with contrast enhancement and possibly integrated positron emission tomography-computed tomography (PET/CT) are performed. If the nodule lacks calcification on the chest CT scan, it is indeterminate.^{2,3}

Positron emission tomography (PET) and integrated PET/CT scanning have recently become important adjuncts in the armamentarium of general thoracic surgeons. PET/CT has helped physicians investigate an

indeterminate pulmonary nodule that is larger than 8 mm (smaller nodules that are malignant can be missed by PET/CT). If the nodule has glucose avidity and a maximum standard unit value (maxSUV) of 2.5 or greater, it has a significant chance (>90% in our series) of being malignant.⁴ In a study by Bryant and Cerfolio⁵ of 585 patients, 496 patients had a malignant nodule, and their median maxSUV was 8.5. Eighty-nine patients had a benign nodule, and the median maxSUV was 4.9 ($P < 0.001$). They observed that if the maxSUV was between 0 and 2.5, the chance that the nodule was malignant was 24%; between 2.6 and 4.0, it was 80%; and for 4.1 or greater, it was 96%. False-negative results occurred from bronchoalveolar carcinoma in 11 patients, carcinoid in 4 patients, and renal cell in 2 patients. False-positives included fungal infections in 16 patients.⁵ Similarly, enlarged mediastinal lymph nodes with a maxSUV of greater than 2.5 are likely to be malignant; we have shown that a lymph node with a maxSUV of 5.3 or greater has a 92% chance of being malignant.⁶ Patients with lymphadenopathy on CT scans or uptake on PET/CT scans should have mediastinoscopy, endoscopic ultrasound fine-needle aspiration, or endoscopic bronchial ultrasound examination to obtain tissue diagnosis before a surgical resection. If the CT and PET scan results are equivocal or abnormal, resection is usually best in patients who are good candidates for surgery.

Needle biopsy, by either a transthoracic route or a transbronchial route, rarely changes the management of this type of nodule, especially if there is no lymphadenopathy. Definitive diagnosis is really achieved only with excisional biopsy, which can be performed by a video-assisted approach, an open technique, or by robotic assisted thoracoscopy, depending on many variables that

are discussed elsewhere in this text. Navigational bronchoscopy can be a helpful adjunct in the workup of these lesions, especially if the lesion is small and deep in the tissue. It allows the surgeon to biopsy the nodule (which may or may not change the need for resection) and to mark deeper lesions that are not palpable during minimally invasive surgery. In addition, biomarker panels may one day be helpful in determining whether solitary pulmonary nodules represent cancer, as opposed to a benign lesion.⁷

In this chapter, we discuss the most common benign tumors of the lung (adenomas and hamartomas constitute the largest group of benign lung tumors) and highlight the important clinical factors associated with each one. Each section is organized in the following fashion to help the reader: definition, incidence, special history or physical examination findings, unique radiologic characteristics, intraoperative tips for resection if indicated, pathologic characteristics, and special postoperative care or follow-up care, including the risk of recurrence. Box 10-2 lists the radiographic characteristics typical of benign lesions.

HAMARTOMA

Hamartomas are the most common benign lung lesions and account for more than 70% of all nonmalignant tumors of the lung.⁸ They are mesenchymal tumors with a peak incidence in the sixth decade of life, and approximately 90% are asymptomatic. Men are affected twice as often as women are. Ninety percent of these tumors appear as solitary peripheral nodules and account for approximately 4% of all solitary pulmonary nodules (Fig. 10-1). The 8% to 10% of hamartomas with presenting symptoms such as cough, hemoptysis, and recurrent pulmonary infections are usually endobronchial lesions. Resection of these lesions is usually needed, even when a definitive biopsy has been performed on them and they are proved to be benign because they cause local problems from airway obstruction. These problems include recurrent pneumonia, parapneumonic empyema, hemoptysis, and cough. Laser ablation can be used to help open the airway, but complete resection is preferred.

Cartilage is present in most lesions and is diagnostic of a hamartoma. There are usually nests of cartilage surrounded by cellular fibrotic tissue. Mature fat cells are a frequent component, and their presence on CT scan (low Hounsfield units) is strong evidence for the diagnosis of a hamartoma.⁹ Rarely, bone, vessels, bronchioles, and smooth muscle are found. On gross examination, the bosselated appearance is typical for a hamartoma. The usual size is 1 to 3 cm, with the lesion being round and firm. They are easily shelled out from the surrounding lung tissue (Fig. 10-2). As with any indeterminate pulmonary nodule, lung-preserving techniques are best if possible.

On radiographic examination (Fig. 10-3), hamartomas are peripheral lesions that are most often located in the lower lung fields and are well circumscribed. The majority are less than 4 cm in diameter, and calcifications can be appreciated on radiographs in 10% to 30% of cases

BOX 10-2 Radiographic Characteristics of Benign Nodules

- Nodular lesions with “tails” toward the hilum include rounded atelectasis (usually has thickening of the associated pleura as well), arteriovenous malformations, and occasional bronchogenic cysts.
- Lesions that are connected to blood vessels include nodular pulmonary infarcts, occasional solitary metastatic lesions, arteriovenous malformations, and bronchopulmonary sequestrations.
- Multiple peripheral triangular or rounded lesions with cavitation and with pulmonary artery branches leading up to them suggest septic embolization.
- In cavitating nodules, wall thickness provides diagnostic information. Thin-walled (<1 mm) cavities are uniformly benign, and 90% of cavitated nodules with wall thickness of 1 to 4 mm are benign. In contrast, cavitated nodules with a wall thickness greater than 16 mm are nearly always malignant.
- Nodules surrounded by a halo may be noted in the setting of angioinvasive aspergillosis, zygomycosis (mucormycosis), lymphoma, bronchioloalveolar carcinoma, coccidioidomycosis, and (rarely) bacterial infections.
- Nodules composed predominantly of ground-glass opacification (nonsolid nodules) can be seen in bronchioloalveolar carcinoma.
- Eighty percent of nodules smaller than 2 cm are benign; 90% of those larger than 3 cm are malignant, yet 40% of malignant nodules are smaller than 2 cm.
- Nodules surrounded by small satellite lesions are benign 90% of the time.
- Nodules with a doubling time of less than 30 days or greater than 480 days are usually benign. Bronchioloalveolar carcinoma is an exception to this rule and may have a radiographic doubling time of more than 700 days. Epstein-Barr virus-associated lymphoma or lung cancer in HIV-positive patients can have fast doubling times.

Data from Henschke CI, Yankelevitz DF, Mirtcheva R, et al: CT screening for lung cancer: frequency and significance of part-solid and nonsolid nodules. AJR Am J Roentgenol 178:1053–1057, 2002; and Tsubamoto M, Kuriyama K, Kido S, et al: Detection of lung cancer on chest radiographs: analysis on the basis of size and extent of ground-glass opacity at thin-section CT. Radiology 224:139–144, 2002.

(Fig. 10-4). Calcifications are described as being “popcorn-like” or “diffuse.” Hamartomas display a slow growth rate (≈ 3 mm/yr) and are rarely multiple. Although it is identifiable in only half of the cases, fat density as identified with CT scan (low Hounsfield units) is strongly suggestive of a benign hamartoma.^{10,11} Endobronchial lesions are not identifiable with radiographic examination unless distal parenchymal changes have occurred (e.g., pneumonia or atelectasis).

Although percutaneous transthoracic needle aspiration yields a definitive diagnosis in up to 85% of cases, only a positive and specific result negates the need for excisional biopsy. Depending on the location, lesions might be amenable to resection by video-assisted thoracoscopic surgery (VATS). For hilar or central tumors that would necessitate a greater resection, such as pneumonectomy, endobronchial ultrasound guided

FIGURE 10-1 ■ CT scan of the chest showing a chondroid hamartoma measuring 1.4×1.7 cm in the inferior lingula of the left lung. The patient was a 49-year-old woman with a normal PET scan. Because her clinical presentation was suggestive of malignant disease, a left upper lobe wedge resection was performed. Ninety percent of hamartomas are located in the periphery, and they account for about 4% of all solitary lung nodules.

FIGURE 10-2 ■ Cut surface of a resected hamartoma.

fine-needle aspiration may be helpful in establishing a benign diagnosis of hamartoma and avoiding resection. Unlike cartilaginous tissue in normal bronchi, the cartilage in hamartomas tends to show irregular size, shape, and arrangement of chondrocytes and prominent empty

FIGURE 10-3 ■ Lateral chest radiograph showing a round lesion consistent with a hamartoma.

FIGURE 10-4 ■ **A**, Right lung hamartoma. The lesion was resected, and a benign process was confirmed. Lesions are most often located in the lower lung fields and are well circumscribed. **B**, The majority are less than 4 cm in diameter, and calcifications can be appreciated on radiographs in 10% to 30% of cases.

lacunae.¹² Given the potential for malignant transformation, continued observation of these lesions is warranted. Endobronchial lesions obstructing the airway may be amenable to bronchoscopic resection with either a snare or neodymium-yttrium-aluminum garnet laser resection, although long-term follow-up data on recurrence risk are not available.¹³ Historically, most of these patients have undergone sleeve resection.

Carney triad is found infrequently and consists of a gastric epithelioid leiomyosarcoma, a functioning extra-adrenal paraganglioma, and a pulmonary hamartoma.^{11,14} Most commonly, the gastric lesion is the first lesion identified, followed by the extra-adrenal paraganglioma.

Although hamartomas are benign per se, several cases of malignant transformation arising at the resection site have been reported.¹⁴ However, it appears that these synchronous or metachronous carcinomas are coincidental because the frequency is less than 7%. The etiology of these malignant neoplasms and their relationship to the hamartoma remain unknown.

MUCOUS GLAND ADENOMA

Mucous gland adenoma is a rare, benign tumor arising from the mucous glands of the bronchus; it is also known as *bronchial cystadenoma* and *mucous cell adenoma*. The exact incidence of these tumors is unknown, although several small series of case reports have been published. To be classified as a mucous gland adenoma, a tumor must contain cystic glands that are superficial to the cartilaginous plate, be in the bronchus, and contain features of normal bronchial seromucous glands. On histologic examination, numerous small mucus-filled cysts lined by well-differentiated epithelium are observed (Fig. 10-5).¹⁰

These benign lesions are typically exophytic in nature and cause bronchial obstruction; therefore, they usually appear because of hemoptysis, recurrent pneumonia, and persistent cough. Because of their nonspecific symptomatology, mucous gland adenomas may go undiagnosed for a prolonged period of time.¹⁵ The lesion itself does not have distinguishing radiographic features, but the chest radiograph may show obstructive pneumonitis. CT scan may demonstrate an intraluminal mass, while bronchoscopy reveals a firm, smooth, shiny, and well-defined mass that may be pedunculated.¹⁶ These noninvasive tumors are evenly distributed between the left and right lungs, with the major bronchi of the lower lobes being affected more often. The lesions are soft, spherical, and polypoid with an average diameter of 18 mm; however, lesions greater than 6 cm in size have been reported.^{11,16} Although the lesions rarely have a stalk, stalks can be completely removed endoscopically by curettage, cryotherapy, or laser ablation. Surgical resection is indicated only if the distal lung tissue is destroyed or chronically infected.

INFECTIOUS GRANULOMATOSIS

Infectious granulomas cause approximately 80% of benign nodules.^{14,17} Endemic fungi (e.g., histoplasmosis,

FIGURE 10-5 ■ Photomicrograph of a mucous gland adenoma.

coccidioidomycosis) and mycobacteria (either tuberculous or nontuberculous mycobacterial disease) are the most frequently recognized causes of infectious granulomas presenting as a solitary peripheral nodule. Especially in regions where granulomatous fungal disease is endemic (e.g., coccidioidomycosis in the Southwest and histoplasmosis in the Mississippi, Ohio, and lower Missouri River Valleys), the chances of an FDG-avid pulmonary nodule being lung cancer may be diminished. Working in an area where histoplasmosis is prevalent, Deppen and colleagues¹⁸ found that the specificity of PET scan for lung cancer was only 40% for lesions with a maxSUV greater than 2.5, compared with a recent meta-analysis that estimated it at 83%.¹⁸ When nontuberculous mycobacterial disease manifests as a solitary peripheral nodule, the cause of the nodule is typically unrecognized until the lesion is resected as a presumed primary lung cancer. In patients with acquired immunodeficiency syndrome, *Pneumocystis jiroveci* (previously called *Pneumocystis carinii*) infection can manifest as a solitary peripheral nodule and may cavitate.

INTRAPULMONARY FIBROUS TUMOR

Intrapulmonary fibrous tumors are contiguous with the visceral pleura and are identical to localized fibrous tumors of the pleura. Terms such as intraparenchymal localized fibrous mesotheliomas, intrapulmonary fibrous mesotheliomas, localized fibrous tumor of the pleura, and inverted fibrous tumor of the pleura have been used and are essentially interchangeable. The visceral pleura is the most common location of these tumors, but they also have been found in the retroperitoneum, mediastinum, and parietal surfaces of the intra-abdominal viscera. The tumors are round to oval and contain a smooth cover of visceral pleura (Fig. 10-6). Most lesions are less than 10 cm in diameter, and histologic examinations show spindle cells with oval nuclei, diffuse fine chromatin, and positive staining for vimentin and the surface receptor CD34.¹⁹ In most cases, the tissue of origin is the mesenchymal layer of the visceral pleura. No distinctive radiographic features are known for these lesions, although the radiologist often includes a malignant mesothelioma in

FIGURE 10-6 ■ The arrow indicates an intrapulmonary fibrous tumor. Lesions are contiguous with the visceral pleura. Tumors are round to oval and are usually less than 10 cm in diameter.

the differential diagnosis. The obtuse angle that these tumors make with the chest wall strongly suggests that the tumor is arising from the pleura and not from the lung. Unlike diffuse mesotheliomas, intrapulmonary fibrous tumors are not related to asbestos exposure. Surgical resection is usually performed by VATS. Solitary fibrous tumors, whether intrapulmonary, polypoid, or sessile, are usually benign, but up to 10% are malignant. The morphologic appearance of the tumor cannot be used to differentiate between benign and malignant tumors. The recurrence risk for patients with completely resected benign solitary fibrous tumors is very low, but not zero; however, patients with a malignant solitary fibrous tumor have a significantly higher risk of recurrence, and a 5-year survival that approaches 50%, as opposed to 90% in patients with benign solitary fibrous tumors.²⁰

BENIGN ENDOBRONCHIAL FIBROUS HISTIOCYTOMA

A fibrous histiocytoma is a benign lung tumor that is composed of collagen and inflammatory and mesenchymal cells. These lesions are rare endobronchial lesions that occur most often in either children or young adults. Because they are so rare, their exact incidence is unknown. No specific radiographic findings distinguish these lesions from others. Depending on the location or the extent of bronchial involvement, surgical therapy might entail a lobectomy or sleeve lobectomy. Bueno and coworkers²¹ described bronchoplastic resections of five endobronchial fibrous histiocytomas.

GRANULAR CELL TUMOR

Granular cell tumors, also called *granular cell myoblastomas*, are another type of rare, benign tumor. These tumors initially were thought to derive from skeletal muscle; however, evidence now suggests that these lesions originate from Schwann cells, as Deavers and associates²² described in 20 cases. In half of the patients, the lesion

was an incidental finding. In the other half, symptoms were caused by obstruction, including postobstructive pneumonia and atelectasis. The lesions were solitary in 75% of the cases. Chest radiographs showed lobar infiltrates, coin lesions, and atelectasis. Tumors usually are located in a large bronchus and can protrude into the bronchial lumen, but they also can be found in the pulmonary parenchyma. Tumors usually are circumscribed but not encapsulated and range in size from 0.3 to 5.0 cm. Nearly all granular cell tumors stain positive for S-100; unlike melanoma, which also stains positive for S-100, granular cell tumors are negative for HMB-45.²³ Complete resection is curative, although recurrences have been described.²² Epstein and Mohsenifar²⁴ reported the use of neodymium-yttrium-aluminum garnet laser to treat obstructing lesions.

INFLAMMATORY PSEUDOTUMOR

Inflammatory pseudotumors are usually asymptomatic solitary nodules that are found on routine chest radiography or CT scan.²⁵ They can be large or be primarily of the airway (Fig. 10-7). Because these tumors go by many other names, such as plasma cell granuloma–histiocytoma complex, plasma cell granuloma, histiocytoma, xanthofibroma, and xanthoma, there is often confusion. Inflammatory pseudotumors usually are well-circumscribed, nonencapsulated, firm, white or yellow masses. They can occur at any age and they are found equally in men and women. Two major groups have been identified: fibrohistiocytic and plasma cell granulomas. In both groups, the histologic examinations reveal a mixture of inflammatory cells, including plasma cells, lymphocytes, and macrophages. Some reports have shown that there may be two types of inflammatory pseudotumors.²⁵ Fibrohistiocytic inflammatory pseudotumors are

invasive, large, and more difficult to resect as opposed to plasma cell granuloma inflammatory pseudotumors, which are characterized by a small, easily wedged mass without evidence of local tissue invasion. The mechanism for these two types is unclear, although it appears microscopically to depend on the degree of inflammatory cells present. A clinicopathologic series from the Massachusetts General Hospital provided evidence that organizing pneumonia may be the nidus for the formation of inflammatory pseudotumors. *Cryptococcus*, *Histoplasma*, and *Actinomyces* spp. infections have been associated with the development of inflammatory pseudotumors.^{26,27} Excision of these lesions is usually both diagnostic and curative. The 10-year survival rate of patients following resection for inflammatory pseudotumors approaches 90%.²⁸ However, the clinical behavior of inflammatory pseudotumors is variable; they can exhibit aggressive local growth and the capacity to metastasize.^{29,30} In patients with multiple lesions not amenable to excision, radiation therapy and corticosteroid therapy are other options.

Although primary lung tumors are infrequent in childhood, plasma cell granuloma is the most common lung lesion in the preadolescent age category. Serial chest radiographs usually show the nodule to be unchanged in size, and it may even shrink without treatment in some patients. Slow growth occurs in less than 10% of cases.³¹ On CT scans, these lesions appear as a well-margined, lobulated mass with some heterogeneous attenuation.

PAPILLOMAS

Papillomas are classified as squamous, glandular, or mixed, and typically present as endobronchial lesions. Squamous papilloma is a benign epithelial neoplasm formed by squamous epithelium. Papillomas of the endobronchial tree have been classified into two main groups: multiple squamous papillomas and solitary papillomas. Drennan and coworkers³² also distinguished a third class, inflammatory polyps.

Multiple squamous papillomas are usually seen in children with laryngeal papillomatosis, usually caused by human papillomavirus. Children can become infected during vaginal childbirth because their oropharynxes and respiratory systems are exposed during the delivery. Serotypes 16 and 18 can act as promoters in carcinogenesis. On gross examination, the papillomas can be exophytic and may have a component outside the bronchial wall and endophytic and obstruct part of the airway. There may be distal bronchiectasis with atelectasis or consolidation of the surrounding lung. Papillomas have a connective tissue stroma that often is heavily infiltrated with lymphocytes and covered completely with cuboidal or squamous epithelium.

Solitary squamous papillomas are rare and affect middle-aged men who are smokers. Productive cough, hemoptysis, wheezing, and dyspnea are common complaints resulting from obstruction by the lesion. On histologic examination, they have a thin central fibrovascular core that is covered by stratified squamous epithelium, and they form multiple papillary fronds. Chest

FIGURE 10-7 ■ Inflammatory pseudotumor of the left main-stem bronchus involving the carina. The patient was treated successfully in the past with steroids; however, she has recently become afflicted with multiple pneumonias, and radiographic studies suggest that she has obstruction of the main-stem bronchus. The patient underwent left main-stem bronchial sleeve resection.

radiography may show a lesion or atelectasis. The papillomas usually are located in segmental or more proximal bronchi. The human papillomavirus is the most common cause of these lesions. Squamous papilloma can be associated with dysplasia, carcinoma in situ, or foci of invasive squamous cell carcinoma. Close surveillance and repeated biopsies are sometimes necessary in observing these patients.

Glandular and mixed papillomas are found equally in men and women in an older population than patients with solitary squamous papillomas. These papillomas are not linked with smoking.

Fibrous polyps are another type of endobronchial lesion and can be found solitary or in multiple locations. These polyps usually arise from the bronchial mucosa and have a fibrous stalk. They are covered by ciliated columnar epithelium. The stalk usually is composed of loose connective tissue with an infiltrate of plasma cells, lymphocytes, and eosinophils. These polyps are always benign and may be secondary to chronic inflammatory processes.

Photodynamic therapy and laser or endoscopic removal are some of the options available to treat these lesions. Bronchotomy or sleeve resection usually is not needed.

NODULAR AMYLOID LESION

Nodular amyloid lesions represent a focal collection of amyloid deposition in the lung; they are most frequently found in the lower lobes. They are sometimes referred to as *amyloidomas*. They can occur as solitary or multiple nodules. The following three types have been described: tracheobronchial, nodular pulmonary, and diffuse pulmonary. Although nodular amyloid lesions are not associated with primary systemic amyloidosis, multiple myeloma should be ruled out. Patients are usually asymptomatic, and lesions are discovered incidentally on chest radiography. Patients should be followed up long term because of the association with macroglobulinemia and malignant lymphoma. Surgical resection is usually curative.

CHONDROMA

Chondromas are defined as benign cartilaginous tissue that can occur in the lung parenchyma or in the cartilaginous airways. Endobronchial lesions can cause obstructive symptoms, whereas parenchymal tumors are asymptomatic. Histologic examination of chondromas shows benign cartilaginous tissue. Some patients with this unusual lesion may have Carney triad, which is composed of pulmonary chondroma, multiple gastric smooth muscle tumors, and extra-adrenal paragangliomas.¹¹ The lesions may contain metaplastic bone, mature cartilage, and myxoid stroma. Single lesions are most commonly resected for diagnosis and have an excellent prognosis. When patients have multiple lesions, a tissue sample, often obtained by a minimally invasive approach with a needle biopsy, usually is sufficient to make the diagnosis.

MYOEPITHELIOMA

Myoepitheliomas are rare, benign tumors arising from myoepithelial cells that lie between the epithelial cells of a gland and the basement membrane. Although these lesions are more commonly found in salivary glands and the breast, rare cases have been reported in the lung parenchyma. Strickler and associates³³ described two patients in whom these lesions were found. Both patients had a mass on the chest radiograph. Immunostaining for S-100 was positive, which is consistent with the diagnosis of a myoepithelioma. Surgery appears to be curative. Because these lesions are so rare, pathognomonic radiographic and clinical signs have not been described. Rare cases of the malignant version of this tumor—primary myoepithelial carcinoma of the lung—have also been reported.³⁴

MUCINOUS CYSTADENOMA

Mucinous cystadenoma is a unilocular cystic lesion whose fibrous wall is lined by well-differentiated, benign columnar mucinous epithelium.³⁵ These lesions occur usually in the fifth and sixth decades of life in patients who smoke; however, the exact incidence is unknown. Most patients with this tumor are asymptomatic, and it represents an incidental finding on chest radiography. The lesions usually are located toward the periphery. Once the tumor is excised, the lesion appears as a unilocular cyst filled with gelatinous material. Sometimes the mucin extravasates into the surrounding lung parenchyma. Because these cysts may harbor adenocarcinoma, they should be completely excised. On microscopic examination, these lesions may look similar to a bronchogenic cyst and what was formerly known as *bronchioloalveolar carcinoma*.

ALVEOLAR ADENOMA

Alveolar adenomas are rare tumors characterized by the proliferation of cuboidal alveolar epithelial cells surrounded by a myxoid and collagenous interstitium.³⁶ These lesions are slow growing, well demarcated, and multicystic, and they can resemble normal lung on non-surgical biopsy specimens.³⁷ Yousem and Hochholzer³⁸ reported one of the largest series with six patients, most of them women. Other smaller reports also have been published.⁴ Lesions usually were identified on routine chest radiographs as an indeterminate nodule in the middle lung field. Excision appears to be curative.

LEIOMYOMA

Leiomyomas are benign lesions of the lung that can occur in the trachea, bronchus, pleura, or pulmonary parenchyma itself. Leiomyoma accounts for approximately 2% of all benign lung lesions. Vera-Roman and coworkers³⁹ reviewed the literature and found a female-to-male ratio of 1.5:1 (Fig. 10-8). There are no discrete

FIGURE 10-8 ■ Benign metastasizing leiomyoma. These lesions occur in young women and are associated with leiomyomas of the uterus. **A**, Anteroposterior chest radiograph demonstrating multiple leiomyomas. **B**, The corresponding chest CT scan.

findings on physical examination. Some patients have hemoptysis if an endobronchial component is present; in others, the tumor is an incidental finding on chest radiography. It appears that the distribution between tracheobronchial and parenchymal location is equal. On histologic examination, smooth muscle differentiation is found. Immunohistochemistry can confirm the mesenchymal origin of the tumor, which stains positive for desmin, muscle-specific actin, and vimentin. Some of these lesions stain positively for estrogen and progesterone receptors and can depend on a certain hormonal milieu, which explains why some of these lesions occasionally disappear during pregnancy, the postpartum period, and menopause.⁴⁰ Surgical treatment consists of excision and is the therapy of choice. Endobronchial lesions can occasionally be treated with laser ablation. Otherwise, sleeve bronchoplasty is needed. Benign metastasizing leiomyomas occur in young women and are associated with leiomyomas of the uterus.⁴¹ Treatment for this condition is not standardized, although certain concepts exist. Performing hysterectomy can remove the

source of the metastases. Hormonal manipulation with either pharmacologic means or bilateral oophorectomy, by decreasing levels of estrogen and progesterone, can lead to regression or stabilization of tumor growth. Surgery may be indicated if the lesions are growing in size in spite of therapy, or if diagnostic uncertainty exists.⁴² Although labeled a benign condition, these lesions can metastasize and cause death.

LYMPHANGIOLEIOMYOMATOSIS

Lymphangioleiomyomatosis (LAM) is a rare disease primarily found in women of childbearing age; it was first described in the medical literature by von Stossel in 1937.⁴³ It can be either sporadic or associated with tuberous sclerosis. LAM causes the progressive decline of pulmonary function through cystic degeneration of the parenchyma, and can lead to recurrent chylous pleural effusions and spontaneous pneumothoraces. Morphologically, LAM is characterized by progressive proliferation of spindle cells, resembling immature smooth muscle in the lung parenchyma and along lymphatic vessels in the chest and abdomen. The proliferation of spindle cells along the bronchioles leads to air trapping and eventually to the development of thin-walled cysts, which cause pneumothorax when they rupture. The proliferation of spindle cells impairs lymphatic drainage leading to chylous pleural effusions. Main symptoms stem from either a chylous pleural effusion (up to 80%) or a pneumothorax (30% to 50%). In both cases, dyspnea is the lead symptom.⁴⁴

Radiographic presentation of lymphangioleiomyomatosis includes reticular, reticulonodular, miliary, and honeycomb patterns on plain radiography. The CT scan usually shows multiple thin-walled lung cysts within normal lung parenchyma. The usual diameter of these cysts is between 0.2 and 5 cm. The disease pattern does not spare any lung zones and is distributed diffusely throughout the lungs. Hilar and mediastinal adenopathy are not uncommon. Diagnostic workup includes plain radiography, chest CT scan, and lung biopsy. Biopsy specimens can be obtained by either thoracoscopy or transbronchial biopsy.

The role of the thoracic surgeon for patients with LAM, besides to obtain a diagnostic biopsy, typically revolves around the management of chylothorax and pneumothorax and in some cases lung transplantation. Lung transplantation is the established option for LAM patients who develop end-stage lung failure. Fortunately, research into the mechanism behind LAM has recently led to some therapeutic insights. The smooth muscle cells in patients with LAM possess mutations in the tuberous sclerosis complex gene that result in constitutive activation of the mammalian target of rapamycin (mTOR) signaling pathway. Sirolimus, an inhibitor of the mTOR pathway, has been shown to stabilize the progressive decline in FEV1 typically experienced by patients with LAM.⁴⁵ LAM cells are also known to express the growth factors VEGF-C and VEGF-D, although therapies targeting this cellular growth pathway do not currently exist. Historically, anti-estrogen therapy with either

medications such as tamoxifen or bilateral oophorectomy was used for LAM, but data supporting the efficacy of this treatment strategy are lacking.

CLEAR CELL TUMOR (SUGAR TUMOR)

A clear cell tumor is a benign lesion of the lung of unknown tissue origin. Recent evidence suggests that it originates from either Clara cells (nonciliated bronchiolar epithelium) or epithelial serous cells. Detailed examination of these tumors showed some neuroendocrine differentiation and positive staining for human melanin black or melanosome-associated protein and S-100. On radiographic examination, the lesions are often peripheral and range in size from 1.5 to 3 cm.^{46,47} Excision is curative. The differential diagnosis includes clear cell, carcinoid, and renal cell carcinoma.

PRIMARY PULMONARY THYMOMA

A primary pulmonary thymoma is a thymoma that is present in the lung in a patient with a normal mediastinal thymus gland. Pulmonary thymomas are rare, and their exact incidence is unknown; they can occur peripherally or centrally. By definition, the tumor must be contained within the visceral pleura because ectopic mediastinal thymic tissue can be found in the aortopulmonary window and in the aortocaval groove. No distinctive radiologic features are known. Studies have used immunohistochemistry to confirm the diagnosis. Thymic T lymphocytes must be differentiated from lymphoepithelial-like carcinoma of the lung and from primary lymphomas. Surgical resection usually is curative. In rare cases, when the tumor is extensive and complete resection is difficult, neoadjuvant therapy with radiation has been described (Fig. 10-9).⁴⁸

CONCLUSION

Benign lesions of the lung are rare and often are diagnosed only after complete surgical resection. If a nodule remains indeterminate after a thorough evaluation as described in the preceding sections, resection is best if the patient's risk is acceptable. If surgery is not chosen, careful follow-up is needed to ensure that a malignant neoplasm is not missed. The solitary pulmonary nodule is a common radiologic finding that can require an extensive evaluation to establish a benign or malignant diagnosis. Morphologic evaluation of the size, margins, and contour with conventional imaging techniques alone often is not satisfactory. PET/CT scan has augmented the noninvasive armamentarium available to the general thoracic surgeon; however, careful interpretation of study results is needed. No test supplants tissue biopsy or, in some cases, complete excision. A normal finding on needle biopsy does not exclude a malignant process. The advent of minimally invasive techniques, such as VATS and robotics, may decrease the threshold to intervene on patients with lesions of uncertain significance due to the

decreased morbidity of these procedures compared to lung resection via thoracotomy. Even if the nodule is benign, excisional resection offers peace of mind to the patient and obviates the need for repeated, expensive, time-consuming radiologic tests. For patients with symptoms related to airway obstruction or involvement such as recurrent pneumonia, hemoptysis, and atelectasis, the decision to intervene is more obvious. Selected patients are candidates for endobronchial intervention, whereas others may be better served with parenchyma-sparing resection, such as sleeve lobectomy. Although they are rare, the general thoracic surgeon should be familiar with the different types of benign lesions to counsel his or her patients and to provide a differential diagnosis. The surgeon must be able to interpret the radiographs and also the disease, which often are equivocal in these lesions.

Idiopathic Pleuroparenchymal Fibroelastosis
Unclassifiable Idiopathic Interstitial Pneumonias
Interstitial Lung Disease Associated with Connective Tissue Diseases
Diffuse Alveolar Hemorrhage Syndrome
Lymphangioleiomyomatosis

PATIENT EVALUATION

TREATMENT

Interstitial lung disease (ILD) is a group of more than 200 clinical entities that manifest with chronic, progressive, diffuse inflammation of the pulmonary interstitium. This inflammatory process can result from a primary pulmonary process, or it can be the result of a systemic illness such as a connective tissue disease. ILD does not include inflammatory responses secondary to known malignant or infectious etiologies, and for the purposes of this chapter, it will not include adult respiratory distress syndrome. However, these entities can demonstrate highly similar clinical and radiographic findings, and they are certainly included in the clinical differential diagnosis of immunologic disease of the lung.

The interstitium includes the alveoli, the epithelial and capillary cells within the alveolar wall, the septal tissues, and the connective tissues that surround the vascular, bronchial, and lymphatic structures within the lung parenchyma. An inflammatory response can involve any or all of these structures with varying clinical and radiographic presentations. The pathologic response to the resulting immunologic insult permits a clinically useful, although not strict, categorization of ILD into those entities characterized by alveolitic and diffuse interstitial inflammation and those that result in a predominantly granulomatous pattern of disease (Box 11-1).

Either pathologic response can progress from injury to fibrosis; therefore, all these entities manifest clinically as progressive dyspnea on exertion, a persistent nonproductive, typically paroxysmal, cough in the setting of radiographic interstitial opacities, or as both. Symptoms are usually chronic, progressing over years; however, presentation can be acute, as in allergic responses seen with hypersensitivity pneumonitis, eosinophilic pneumonia, drug-induced alveolitis, or acute interstitial pneumonia, or subacute, as with sarcoidosis, alveolar hemorrhage syndromes, cryptogenic organizing pneumonia, and some of the connective tissue diseases.

Fatigue and weight loss are common. Wheezing, hemoptysis, or pleuritic chest pain can be present, but are relatively rare at presentation. In fact, sudden onset or increased chest pain in the setting of these diseases is more suggestive of spontaneous pneumothorax, particularly in histiocytosis X (pulmonary Langerhans cell histiocytosis), tuberous sclerosis, lymphangioleiomyomatosis, and neurofibromatosis. Hemoptysis is associated with diffuse alveolar hemorrhage syndromes and the granulomatous vasculitides. Disease manifestation in other organ systems is helpful in the diagnosis of granulomatosis with polyangiitis (formerly called *Wegener granulomatosis*) and Goodpasture syndrome. Age, sex,

medical, family, and smoking histories and occupational and environmental exposure all figure prominently in the development of a differential diagnosis for a particular patient. Physical examination usually reveals bibasilar end-inspiratory “Velcro” crackles, but this is less common in the granulomatous diseases. Baseline tachycardia is common. Cyanosis and clubbing can occur with advanced disease.

GRANULOMATOUS PATTERNS OF INTERSTITIAL LUNG DISEASE

Granulomas consist of activated immune cells, typically macrophages, encircling particles that are generally not recognized by the antigen-specific, or adaptive, immune

system. The particle can be a foreign body or an intrinsic protein antigen that activates the innate immune system. Innate immunity is a non-antigen-specific means by which the body provides a first line of defense against foreign pathogens, including inhaled irritants. The innate immune system activates macrophages directly, without any need for prior exposure or antigen processing as is required for an adaptive T and B cell-dependent response. Activated macrophages mature to form epithelioid cells around the foreign material and thereby form a granuloma.¹

Macrophage activation and granuloma formation are also influenced by specific immune signals generated by other cells of the immune system, including signals triggered in an antigen-specific manner by the foreign particle or protein (Fig. 11-1). Fragments of foreign proteins processed by antigen-presenting cells, such as dendritic cells, are displayed on the cell surface in the context of the host major histocompatibility complex (MHC). Through this indirect pathway, antigen-specific CD4⁺ helper T cells are activated in the context of class II MHC presentation; whereas CD8⁺ effector T cells traditionally require the class I MHC complex. These activated T cells produce various cytokines that trigger several antigen-specific and nonspecific cellular subsets. For example, the activated T_H1 subsets of CD4⁺ helper T cells and natural killer cells produce interferon-gamma (IFN-γ), leading to primarily macrophage activation. On the other hand, the T_H2 subset produces interleukin (IL)-4 and IL-5 and results in eosinophil production and activation.¹⁻³ Other T cell subsets, such as CD8⁺ effector cells, are also recruited to help clear the protein antigen and thus help regulate the immune system. Once activated, this inflammatory process results in the recruitment of other immune cells, complement, and growth factors to form discrete granulomas, or the process may spread to the alveolar spaces and walls, leading to alveolitic changes (described later). Tumor necrosis factor (TNF), a potent

- Eosinophilic pneumonias
- Histiocytosis X

ALVEOLITIC

- Drug-associated injury
- Goodpasture syndrome
- Idiopathic interstitial pneumonia
- Interstitial lung disease associated with connective tissue diseases
- Diffuse alveolar hemorrhage syndrome

FIGURE 11-1 ■ Granuloma formation and maturation. **A**, Early accumulation of macrophages around antigen or foreign body. Release of proinflammatory cytokines tumor necrosis factor alpha (TNFα) and interferon-gamma (IFNγ), and chemokines such as macrophage inflammatory protein 1α results in activation of macrophages and recruitment of other immune cells. **B**, Antigen presentation by dendritic cells and macrophages to incoming T cells results in further activation, with development of epithelioid and giant cells. It is at this stage that fibroblasts become activated, resulting in focal areas of fibrosis. **C**, As the granuloma matures, the structure becomes more compact, with giant cells and T cells at the core. The initial helper T cell 1 (T_H1) response leads to the release of T_H2 cytokines as well, with interleukin (IL)-5 recruitment of eosinophils. NK, Natural killer.

inflammatory cytokine, has been implicated in initiating and driving the inflammatory process in many of these pathologic states. Newer targeted therapies for many inflammatory ILDs involve anti-TNF therapies.^{4,5} Granulomatous mechanisms are involved in a variety of pulmonary diseases, yet they all share this fundamental pathophysiologic mechanism. The clinical presentations and findings of these disease entities are described later.

Foreign Bodies and Inorganic Dust

Patients who have inhaled foreign bodies are typically asymptomatic at the time of initial exposure unless the particle is large enough to occlude the tracheobronchial tree. In such cases, as often seen in children, the diagnosis is made by history, confirmed by chest radiography, and, if needed, diagnosed as well as treated via bronchoscopy. However, prolonged exposure to smaller foreign particles, whether organic or inorganic, can lead to a spectrum of pulmonary disease processes. Chronic exposure to metal dusts, such as beryllium, aluminum, and zirconium—foreign particles that cannot be cleared by the mucociliary system or broken down by the pulmonary macrophages—is associated with a marked interstitial granulomatous disease pattern.⁶ Continuous exposure to small organic particles in susceptible individuals can also lead to hypersensitivity pneumonitis, with both alveolitic and granulomatous responses. The effect of a one-time massive exposure to inorganic fine particulate matter is less clear. A large subset of the pedestrians and workers exposed to smoke, dust, and particulate matter after the World Trade Center attacks in 2001 presented with a variety of nonspecific respiratory ailments, often with documented nonspecific histologic changes on lung biopsy. However, their long-term outcomes are not yet known; although recent reports suggest that many have developed a distinct restrictive type of respiratory dysfunction.⁷⁻¹¹

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis, also known as *extrinsic alveolitis*, describes a pulmonary disease process characterized by immunologically induced injury of the lung parenchyma with granuloma formation, alveolitis, and an antibody response, as the result of repeated exposure to inhaled protein antigen.¹²⁻¹⁴ Numerous antigens have been implicated, from *Aspergillus* spp. and fish meal dust to male rat urine, leading to various interesting, occupation-associated disease names (Table 11-1). Initial exposure to the antigen induces neutrophil and macrophage extravasation to the distal bronchioles and alveoli, thus leading to early alveolitis. Patients may present acutely with cough, fever, and chills several hours after exposure. With continued antigen exposure, patients develop a persistent cough with worsening dyspnea secondary to granuloma formation within the pulmonary parenchyma, and progressive interstitial disease.^{12,14}

Diagnosis relies on careful history taking, with particular emphasis on occupational and recreational exposures. Chest radiographs have no specific diagnostic pattern, although a reticular nodular pattern consistent

TABLE 11-1 Selected Hypersensitivity Pneumonitis Syndromes

with interstitial lung disease may be present. Chest computed tomography (CT) is typically nondiagnostic as well.^{13,14} Bronchoalveolar lavage (BAL) may be helpful, showing an increase in CD4⁺ T cells acutely and CD8⁺ T cells chronically. However, this only marginally narrows the spectrum because this finding is characteristic of nearly all granulomatous disease processes. Serum tests for antibodies to the suspected antigen are often required to make a diagnosis. Lung biopsy, either transbronchial or using video-assisted thoracoscopic surgery (VATS) or open thoracotomy, may be necessary to make a diagnosis in patients for whom other evidence is lacking. Even this aggressive approach, however, may be nondiagnostic in late stages when the acute granulomatous and alveolitic changes are replaced by interstitial fibrosis.

Treatment consists of removing exposure to the suspected antigen, and steroids for patients with the severe acute form of the disease or with chronic persistent fibrosis.¹³⁻¹⁶ Histologic evidence of fibrosis in lung biopsy specimens is correlated with a worse prognosis.¹⁵ Radiologic evidence of fibrosis seen on high-resolution CTs may serve as a surrogate for histologic findings once the diagnosis has been made, and this may correlate with long-term survival and response to therapy.¹⁶

Infections

Pulmonary infection with *Mycobacterium tuberculosis* is probably the most common cause of granulomatous lung disease worldwide.^{2,17} Local and disseminated miliary disease lead to granuloma formation in the infected field. Other infectious organisms, such as *Aspergillus* spp. and certain helminths, can also lead to pulmonary granulomatous disease.² Radiologic assessment alone is often inadequate to make a diagnosis, and the clinical context must be taken into account. The clinical pathogenesis, presentation, course, and treatment of pulmonary infections are discussed elsewhere in this book and are not included in this discussion of ILD.

Sarcoidosis

Sarcoidosis is a chronic systemic disorder that, although common, is still poorly understood. Various organ systems of these patients are often affected by granulomatous disease, and some individuals do not manifest

pulmonary involvement.¹⁸⁻²⁰ The incidence of sarcoidosis varies with the population studied. In Western populations, the incidence is estimated to be 10 to 20 per 100,000 population, with a higher rate in women and those of African American ancestry.²¹ Sarcoidosis is uncommon in Asian populations. Although the disease can manifest at any age, most patients present between the ages of 20 and 40 years.^{18,19,22,23}

The etiology of sarcoidosis is unknown. Environmental, infectious, hereditary, and immunologic factors have been postulated, with variable evidence to support each hypothesis.²³ The interstitial granulomatous disease that results from inhalation of metal dusts is pathologically identical to sarcoidosis, suggesting that an unknown environmental exposure may be responsible.^{6,24,25} Supporters of an infectious etiology argue that the causative agent must be inhaled, because 80% of affected individuals have pulmonary and mediastinal lymph node involvement. In fact, BAL of individuals with extrapulmonary sarcoid contains inflammatory cells even without evidence of pulmonary disease. The causative agent is suggested by some to be *Mycobacterium tuberculosis* or a nontuberculous mycobacterium. Genetic analyses of affected tissue by polymerase chain reaction as well as antibody analysis of afflicted individuals have been inconclusive. Other agents implicated have been *Yersinia enterocolitica* and *Borrelia burgdorferi*, but the evidence linking these agents to sarcoidosis is even less well established. There is familial clustering of the disease, and sarcoidosis has been linked to human leukocyte antigens (HLA) A1 and B8 in whites, suggesting that hereditary and genetic factors play an important role in this disease. Putative genes involved in the pathogenesis of the disease include butyrophilin-like 2 (BTNL2), a T cell costimulatory molecule, annexin A11, as well as polymorphisms in several cytokines and chemokines.²⁶⁻²⁸ Non-MHC immunologic factors are probably also involved, as patients with sarcoidosis have numerous abnormalities of the immune system, including altered T cell ratios, poorly responsive CD4⁺ T cell subsets, hyperactive B cell lines, and altered production of the inflammatory cytokines IFN- γ and RANTES by macrophages.²⁹⁻³³

Symptoms of sarcoidosis are variable and fluctuate with time. Most patients in whom the disease is identified by routine chest radiography are asymptomatic. Others may exhibit the acute onset of constitutional symptoms such as fever, chills, fatigue, and weight loss. Afflicted individuals often have an associated connective tissue disorder, such as rheumatoid arthritis, systemic lupus erythematosus, or progressive systemic sclerosis. Pulmonary symptoms commonly include dyspnea and a dry cough.²² Diagnosis is typically made radiographically, with chest radiographs showing bilateral hilar and mediastinal lymph node enlargement with or without an accompanying reticulonodular pulmonary pattern indicative of interstitial disease (Fig. 11-2). Consolidation and a ground-glass parenchymal pattern may also be evident, particularly on chest CT. Fibrosis is seen in later stages of the disease. Serum abnormalities can include an increase in levels of angiotensin-converting enzyme, presumably produced by the activated macrophages in the granulomas. A preponderance of lymphocytes in

FIGURE 11-2 ■ Computed tomography of the chest from a patient found to have noncaseating, non-necrotizing granulomata in the mediastinal lymph nodes on cervical mediastinoscopy. These findings are consistent with the diagnosis of sarcoidosis. **A**, Lung window. **B**, Mediastinal window.

the BAL suggests an alveolitic process with granulomatous changes. Diagnosis, however, is most often made by mediastinal lymph node biopsy if adenopathy is present.^{22,34,35} In rare cases, transbronchial or VATS biopsy may be needed to establish the diagnosis. Histologic findings of affected pulmonary tissue show noncaseating granulomas with high tissue angiotensin-converting enzyme levels.

Treatment consists primarily of steroids in symptomatic patients.²² Second-line agents such as hydroxychloroquine, methotrexate, leflunomide, azathioprine, and mycophenolate mofetil have also been used for refractory cases. Recent studies have suggested a benefit to tumor necrosis factor inhibitors such as infliximab or adalimumab in patients with poor responses to standard immunosuppressive regimens.^{27,36-41} These therapies are potentially toxic, and patients should be monitored carefully.

Granulomatous Vasculitides: Granulomatosis with Polyangiitis and Churg-Strauss Syndrome

Like sarcoidosis, granulomatosis with polyangiitis (GPA; formerly referred to as *Wegener granulomatosis*) is a systemic disorder characterized by granuloma formation within multiple organ systems. GPA is a rare disease with an incidence of 1 to 3 in 100,000. Affected individuals typically present between the ages of 40 and 60 years.⁴²

In its most extreme form, GPA is characterized by necrotizing granulomatous involvement of the pulmonary parenchyma and both pulmonary and renal vasculature.^{2,25,42-46} Disease expression is variable and may be limited to the pulmonary system. Numerous etiologies have been suggested, including infectious organisms such as parvovirus B19 and other respiratory agents, inhaled environmental agents such as silica, and genetic factors linked to the HLA alleles DR1, DR2, and DR12. Although all these possible etiologies are supported by some evidence, no explanation is conclusive. The sera of individuals afflicted with the disease contain antibodies to antineutrophil cytoplasmic antibodies (ANCA). Specifically, 90% of patients with GPA have C-ANCA, which chiefly binds to the PR3 plasma serine proteinase in neutrophils, as opposed to P-ANCA, which are antibodies to a perinuclear myeloperoxidase enzyme.^{25,43,44} The exact role of C-ANCA in the pathogenesis of GPA is unclear and, unfortunately, ANCAs are also found in other disease states, such as systemic lupus erythematosus, in which ILD may develop.^{25,43-47}

Individuals with GPA may present with fulminant disease, with massive hemoptysis and renal failure secondary to extensive necrotizing granulomatous lesions, or with more subtle findings of fever, malaise, weight loss, and progressive dyspnea, with hemoptysis appearing only as the disease progresses. Neurologic or ocular symptoms may also be present. Diagnosis relies not only on the history, but also on laboratory studies such as C-ANCA serologies and other associated systemic abnormalities.^{25,43,46} Chest imaging shows a reticulonodular pattern consistent with interstitial disease or discrete nodules in only 50% of affected individuals. Central necrosis in these nodules can give the appearance of cavitary lesions (Fig. 11-3). BAL fluid from patients with GPA contains

FIGURE 11-3 ■ Computed tomography of the chest from a young man with Wegener granulomatosis. Central necrosis in a granulomatous lesion has the appearance of a cavitary lesion. Many other such lesions were present throughout the lung parenchyma.

neutrophils and eosinophils. Biopsy of pulmonary or renal lesions may be necessary to establish or confirm the diagnosis. Pathologic analysis typically shows granulomas with neutrophils, macrophages, and eosinophils. Treatment options vary with the severity of the disease and include steroids and immunosuppressive agents, such as cyclophosphamide and methotrexate.⁴⁶ Rituximab, an anti-CD20 monoclonal antibody that targets B cells, has been used in some cases refractory to cyclophosphamide or methotrexate.^{48,49}

Churg-Strauss syndrome is a rare systemic disorder characterized by eosinophilia, vasculitis, and pulmonary parenchymal granuloma formation. Many view this disease as part of a spectrum of disease that includes GPA and other connective tissue diseases.^{25,44,45} The true incidence is unknown because of the difficulty of establishing a diagnosis, but it is estimated at 1 to 2 per 1 million people, and it affects individuals between the ages of 20 and 50 years.^{25,50} As in GPA and sarcoidosis, multiple etiologies have been suggested, including pigeon exposure, helminth infection, and cocaine use. Churg-Strauss syndrome has been associated with the weaning of steroids in asthma patients placed on leukotriene antagonists.^{25,45,51,52}

Affected individuals typically have a history of asthma or allergic symptoms and present with fever, cough, and occasionally hemoptysis. Gastrointestinal bleeding or neuropathy may also be present. Diagnosis rests on clinical suspicion and the combination of symptoms, laboratory studies, and pathologic findings. Chest radiographs typically reveal patchy consolidation throughout the lung fields. Levels of immunoglobulin E and P-ANCA may be elevated. The BAL fluid shows large numbers of eosinophils.^{34,35} A lung biopsy specimen, usually required for diagnosis, demonstrates vasculitis and parenchymal granulomas with eosinophils. Treatment consists of steroid therapy and other immunosuppressive agents such as cyclophosphamide, methotrexate, azathioprine, or mycophenolate mofetil. Intravenous anti-TNF, interferon- α therapy, gammaglobulin, and plasma exchange has also been investigated with some success in refractory cases.^{48,49,53,54} Prognosis for those diagnosed with the syndrome is poor, with a mortality of 50% to 60% at 5 years.^{44,45}

Eosinophilic Pneumonias

Eosinophilic pneumonia belongs to a spectrum of pulmonary processes that are distinguished by the accumulation of eosinophils in parenchymal tissue. Eosinophilic pulmonary diseases with known etiologies include those caused by helminth infections, such as *Strongyloides stercoralis* and *Ancylostoma duodenale*, and drug allergies, which cause peripheral blood eosinophilia and can have systemic effects, as well as those conditions associated with the granulomatous vasculitides (discussed earlier) in which the etiology is unclear.^{55,56} All these disease states can have pulmonary involvement. Diagnosis is made by history, blood eosinophil counts, blood serologies, and occasionally lung biopsy.

Idiopathic eosinophilic pneumonias can be divided into simple, acute, and chronic forms. Simple eosinophilic

pneumonia, also known as *Löffler syndrome*, is rare and characterized pathologically by interstitial edema with abundant eosinophils. Patients typically exhibit few or no symptoms. Chest radiographs show patchy parenchymal consolidation, and the diagnosis rests on the demonstration of peripheral blood eosinophilia in patients with a history of asthma or atopy. The disease usually resolves spontaneously; therefore, biopsy or BAL is rarely required to make a diagnosis. Patients with symptoms, even when symptoms are prolonged, may benefit from steroid therapy.^{55,56}

Acute eosinophilic pneumonia is a rare disorder that manifests as an acute illness with severe respiratory distress that may require ventilatory assistance. The etiology is unclear, but it is thought to be secondary to an eosinophil-mediated immune response to an unknown allergen. Patients present with severe shortness of breath and pleuritic symptoms. Chest radiography shows reticular opacities similar to the pattern found with interstitial pulmonary edema. The disease is characterized by a high number of eosinophils, up to 80%, in the BAL. Steroids are the mainstay of treatment, but a high relapse rate is associated with this disease.^{55,56}

Chronic eosinophilic pneumonia has a similar histologic and, in most cases, radiographic appearance. Again, diagnosis relies on the demonstration of peripheral blood eosinophilia in patients with a history of asthma or atopy. However, affected patients have chronic symptoms that do not resolve over time; therefore, eosinophilia on BAL fluid, tissue biopsy specimen, or both are often needed to make the diagnosis.^{55,56} Steroid treatments usually result in rapid disease regression.^{55,56}

Pulmonary Langerhans Cell Histiocytosis

Histiocytosis X, also known as *eosinophilic granuloma*, *pulmonary Langerhans cell histiocytosis*, or *Langerhans cell granulomatosis*, is a rare disorder characterized by the peribronchial accumulation of specialized antigen-presenting cells known as *Langerhans cells*. Letterer-Siwe and Hand-Schüller-Christian diseases are variants typically found in children and may not have pulmonary involvement.^{57,58} The adult form—eosinophilic granuloma—is characterized by pulmonary and skeletal system involvement. Although rare, histiocytosis X predominantly occurs in whites and in women. Viral infection with Epstein-Barr virus or other members of the herpesvirus family has been suggested as a possible etiology for this disease.^{57,58} Recent reports find that the clonal population of cells involved in this disease have short telomeres, much like those in other malignancies.⁵³ Telomerase activity has also been correlated with the degree of disease expression.⁵⁹ Chest radiographs in the early stages of the disease show bilateral nodular opacities. With progression of disease, a reticulonodular pattern is noted (Fig. 11-4). Patients are typically asymptomatic at the time of diagnosis in young adulthood. Diagnosis is commonly made by routine chest radiography. Symptomatic patients have a dry cough and shortness of breath. BAL can be useful, as Langerhans cell are abundant in the fluid.^{34,35,58} Lung biopsy can confirm

FIGURE 11-4 ■ Computed tomography of the chest from a patient with pulmonary Langerhans cell histiocytosis.

clinical suspicions in unclear cases, because the demonstration of Langerhans cells infiltrating the pulmonary bronchioles is pathognomonic of this disease. Despite the disease name, granulomas are not formed in the strict sense, because the chief cellular component in these lesions is Langerhans cells and not macrophages. Long-standing disease leads to interstitial fibrosis. Remission can occur spontaneously, and it can often be aided with steroid therapy.⁶⁰

ALVEOLITIC PATTERNS OF INTERSTITIAL LUNG DISEASE

When immunologic injury is directed primarily toward the alveolar epithelial surface, inflammation of the alveolar wall and airspaces results in a histopathologic pattern of alveolitis. Both cellular and humoral components of the immune system are involved in these alveolitic changes in the lung. Alveolitic mechanisms are involved in a variety of pulmonary diseases (see Box 11-1).⁶¹

Activated macrophages, T cells, and inflammatory cytokines can lead to B cell activation and antibody production. These antibodies form complexes with the antigen and are deposited within the lung parenchyma, leading to the activation of complement. Although the formation of the membrane attack complex is an attempt to destroy the antigen, injury to the surrounding lung tissue may be significant if this inflammatory reaction is not regulated. A basic diagram of this cascade is shown in Figure 11-5.⁶¹

Chemotactic peptides produced by the complement pathways, such as C5a and C3b, recruit other components of the cellular immune system. Neutrophils and macrophages thus destroy the pathogen and cause further parenchymal destruction. Activated macrophages and other immune cells produce additional cytokines, such as TNF and IL-1, which, together with immune complex deposition and complement activation, lead to direct

FIGURE 11-5 ■ Pathogenesis of alveolitic injury. Activation of alveolar macrophages and polymorphonuclear leukocytes by complement, immune complex deposition, and subsequent cytokine/chemokine release trigger a cascade of responses that result in acute lung injury to the surrounding alveolar membrane and interstitium. *IL*, Interleukin; *TNF*, tumor necrosis factor.

injury to the lung parenchyma and the surrounding vasculature. Numerous other cytokines and inflammatory modulators, such as prostaglandins, can also play important roles in the pathophysiology of ILDs. If the immune process continues unmitigated, the acute inflammatory response present in the lung parenchyma in the early phase of the disease is replaced by increasing degrees of fibrosis as more and more fibroblasts are recruited into the area of injury to repair the damage. Fibrosis is the final common pathway for both the alveolitic and granulomatous immune responses, often making it impossible to differentiate between these two disease processes in the late stages of ILD. Irreversible scarring and fibrosis of the alveolar–endothelial interface and surrounding parenchyma results in significant impairment in gas exchange and is consistent with end-stage ILD. Current investigational treatments focus on mitigating or abrogating the inflammatory response with targeted therapies directed at many of the cytokines involved in the immune response before the development of fibrosis.

Drug-Associated Injury

Whether resulting from direct toxic or immune mediated damage, drug-associated injury to the lung results in an alveolitic pattern of damage. Chronic concomitant damage often leads to irreversible fibrosis. Numerous drugs have been implicated in pulmonary injury, but only amiodarone and its mechanisms are discussed here. Direct toxic effects can result from radiation, bleomycin, nitrofurantoin, and prolonged exposure to high oxygen concentrations.⁶² Injury in these cases is principally the

result of free oxygen radical production. Acute changes are predominantly alveolitic, followed by progressive fibrosis as the lungs recover from the initial insult. BAL specimens from patients during the acute phase contain numerous neutrophils or eosinophils.^{34,35}

Amiodarone, a potent antiarrhythmic agent, has the ability to induce direct and immune-mediated injury. Direct amiodarone toxicity most likely results from the generation of free oxygen radical species. However, the large number of lymphocytes or foamy macrophages indicative of pulmonary phospholipidosis in the BAL suggests that immune-mediated mechanisms are also involved.^{62,63} Pulmonary toxicity has been correlated with patient age and duration of therapy.⁶⁴ However, a fulminant form of amiodarone pulmonary toxicity has been described, especially in patients undergoing lung surgery, and it is thought to be an idiosyncratic immune response.⁶³ Chest radiographs in drug-associated ILD demonstrate an interstitial disease pattern. As fibrosis intervenes, the BAL specimen becomes acellular and the chest radiograph shows a more prominent reticulonodular pattern.^{34,35} Diagnosis rests on the recognition of prior drug exposure. Lung biopsy, if done in late stages, may show only fibrotic change. Treatment of amiodarone pulmonary toxicity consists of prompt cessation of drug use and management of symptoms.

Other common drugs that can cause acute lung injury include statins, which are competitive inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase.⁶⁵⁻⁶⁷ These are uncommon but potentially fatal. Similar to patients with amiodarone toxicity, lymphocytes or foamy macrophages in the BAL is also found in patients with statin induced lung injury. Treatment consists of cessation of statin treatment and symptomatic management.

Goodpasture Syndrome

Goodpasture syndrome is characterized by the presence of pulmonary hemorrhage and glomerulonephritis. Its incidence is rare, it predominantly affects males 15 to 25 years old, and it is linked to the HLA-DR2 MHC allele. Other immunologic and hereditary factors, and an association with free-base cocaine use, have been implicated.⁶⁸ The pathogenesis of alveolitis, pulmonary hemorrhage, and glomerulonephritis results from the presence of antibodies directed against a collagen protein in the alveolar and glomerular membranes. Because of complement activation and cell-mediated injury, these antibodies produce immune complex-mediated injury to lung and renal parenchyma.^{31,69,70}

In most cases, patients present with hemoptysis and occasionally hematuria. Diagnosis is based on clinical symptoms and the characteristic linear staining of the basement membrane with anti-IgG antibodies present on renal biopsy.^{25,31} Chest radiographs demonstrate patchy consolidation secondary to hemorrhage. BAL is nondiagnostic and lung biopsy is rarely needed to make a diagnosis.^{34,35} Therapy consists of plasmapheresis to remove the antibodies, and immunosuppressive therapy.

Idiopathic pulmonary hemorrhage is similar to Goodpasture syndrome in terms of its pulmonary

manifestations. However, this disease predominantly affects children younger than 10 years, and it does not have any renal involvement. Patients exhibit hemoptysis and weakness secondary to iron deficiency. Radiographic appearance is similar to that in Goodpasture syndrome, but the absence of anti-basement membrane antibodies in lung and renal biopsy specimens differentiates between the two. Prognosis is variable, and treatment consists of plasmapheresis and immunosuppressive therapy.³¹

Idiopathic Interstitial Pneumonia

Idiopathic interstitial pneumonias (IIPs) are a spectrum of pulmonary disorders characterized by the infiltration of immune cells into the pulmonary interstitium, and the resultant alveolitic changes. Unabated inflammation leads to fibrosis of the lung parenchyma. Because many terms have been given to the various forms of this disease (Hamman-Rich disease, idiopathic pulmonary fibrosis, usual interstitial pneumonitis, diffuse pulmonary alveolar fibrosis), there has been much confusion in diagnosing this disease entity. A useful subclassification scheme based on pathology has been proposed by Averill Liebow.⁸⁰ An updated modification of this scheme formulated by the American Thoracic Society and European Respiratory Society is presented in Box 11-2.⁷¹ Both societies emphasize a multidisciplinary approach to classifying IIPs incorporating clinical, radiologic, and pathologic findings where warranted. Clinical information such as presentation, exposures, smoking status, associated diseases, and laboratory findings are combined with radiologic findings to make a diagnosis. A lung biopsy is then considered when diagnosis is not possible based on high-resolution chest CT and clinical presentation. Before proceeding with a diagnosis of IIP, all other potential causes such as drug and environmental exposures leading to hypersensitivity syndromes, infectious etiologies, and collagen vascular diseases should be excluded.⁷¹

It has been suggested by some that this classification scheme is arbitrary, with diseases being categorized by distinct names when they may merely be different manifestations of the same disease.⁷²⁻⁷⁴ Nevertheless, as these distinct entities are defined by distinct clinical, radiologic,

and pathologic criteria, they do appear to have their own prognostic indicators and treatment; therefore, it is often useful to distinguish between them whenever possible. We will highlight some of these entities below along with the histologic findings common to these diseases (Table 11-2).

TABLE 11-2 Summary of Histologic Findings for Immunologic Lung Diseases

Disease	Histology
Granulomatous	
Foreign body, inorganic dust	Simple granuloma
Hypersensitivity pneumonitis	Granulomas with CD4 ⁺ /CD8 ⁺ T cells; interstitial edema; fibrosis in later stages
Infections	
Tuberculosis	Caseating granulomas
Sarcoidosis	Noncaseating granulomas
Granulomatous Vasculitides	
Wegener granulomatosis	Necrotizing granulomas involving vasculature
Churg-Strauss syndrome	Necrotizing granulomas involving vasculature
Eosinophilic pneumonias	Granulomas with eosinophilic predominance; interstitial edema
Histiocytosis X	Granulomas with Langerhans cells
Alveolitic	
Drug-associated injury	Interstitial edema with inflammatory cells
Goodpasture syndrome	Linear staining of basement membrane with anti-IgG antibodies typically seen on renal biopsy; interstitial edema with inflammatory cells
Idiopathic Interstitial Pneumonias	
Idiopathic pulmonary fibrosis (IPF)	Interstitial edema and/or fibrosis with inflammatory cells; patchy fibrotic change
Desquamative interstitial pneumonia (DIP)	Interstitial edema with sparse inflammatory cells; mild diffuse fibrotic change
Idiopathic nonspecific interstitial pneumonia (NIP)	Thickened interstitium with inflammatory cells; some patchy fibrosis
Acute interstitial pneumonia (AIP)	Diffuse alveolar damage with thickened fibrotic interstitium; proliferating fibroblasts
Respiratory bronchiolitis-associated interstitial lung disease (RB-ILD)	Macrophages infiltrating distal bronchioles
Cryptogenic organizing pneumonia (COP)	Chronically inflamed alveoli with granulation tissue in bronchioles and macrophages in alveoli
Lymphocytic interstitial pneumonia (LIP)	Diffuse lymphocytic and plasma cell infiltration; minimal alveolar injury
Idiopathic pleuroparenchymal fibroelastosis	Diffuse alveolar damage with fibrosis

BOX 11-2 Idiopathic Interstitial Pneumonias

MAJOR IDIOPATHIC INTERSTITIAL PNEUMONIAS

- Idiopathic pulmonary fibrosis
- Idiopathic nonspecific interstitial pneumonia
- Respiratory bronchiolitis–interstitial lung disease
- Desquamative interstitial pneumonia
- Cryptogenic organizing pneumonia
- Acute interstitial pneumonia

RARE IDIOPATHIC INTERSTITIAL PNEUMONIAS

- Idiopathic lymphoid interstitial pneumonia
- Idiopathic pleuroparenchymal fibroelastosis

UNCLASSIFIABLE IDIOPATHIC INTERSTITIAL PNEUMONIAS

Familial Forms of Idiopathic Interstitial Pneumonia

There have been reports of IIPs occurring in related family members in 5% to 20% of cases.^{71,75-80} These cases are classified on the basis of their clinical, radiologic, and pathologic presentation despite genetic linkage to disease. Mutations have been found in lung surfactant proteins (SFTPC, SFTPA2) and telomerase proteins (TERT, TERC) in patients with familial forms of IIPs.^{71,75-80} These mutations account for at most 20% of familial forms of IIPs.^{71,75-80} Genetic transmission suggests an autosomal dominant mechanism. Familial IIPs cannot be distinguished from non-familial cases on HRCT and lung biopsy. They are suspected only by obtaining family history of lung disorders. Their treatment is dependent on their classification based on clinical, radiologic, and histologic criteria if needed.

Idiopathic Pulmonary Fibrosis

The typical pathologic finding of idiopathic pulmonary fibrosis (IPF) is thickened fibrotic alveolar interstitium infiltrated by inflammatory cells, such as lymphocytes and plasma cells, termed *usual interstitial pneumonia* (UIP). Histologic analysis in the acute phase of the disease demonstrates alveolitis, with an interstitium overrun with inflammatory cells and areas of patchy fibrotic changes.⁷² Patients who demonstrate interstitial lung disease on chest radiography and pathologic evidence of fibrosis on lung biopsy are given this clinical diagnosis when other causes of interstitial disease (e.g., sarcoidosis, hypersensitivity pneumonitis, histiocytosis X, infection) have been excluded.^{71,72,81-85}

IPF occurs with an estimated incidence of 5 to 20 per 100,000 persons, with a slight male predominance.^{50,81,86} The etiology of IPF is unknown. Exposure to heavy metal dusts, solvents, and Epstein-Barr and hepatitis C viruses have all been named as possible mediators of the initial lung injury in susceptible individuals, but there has been no definitive proof for any of these theories.³⁵ Cigarette smoking has been implicated in some case-control studies. IPF has been linked to HLA-B15, HLA-B8, and HLA-B12 loci, and a familial form of IPF has been described, suggesting a hereditary or immunologic component to this disease.^{87,88} Further evidence for an immunologic basis is that individuals afflicted with pulmonary disease related to rheumatoid arthritis, systemic lupus erythematosus, and progressive systemic sclerosis have a high incidence of interstitial inflammation and fibrosis that is clinically and pathologically indistinguishable from IPF. Recent studies have implicated matrix metalloproteinases (MMPs) in the pathogenesis of IPF based on microarray analysis and the results of MMP knockout mice. The diagnostic and therapeutic implications of these findings have not been determined.^{89,90}

Individuals with IPF have progressive shortness of breath, weight loss, and a nonproductive cough. In 80% of individuals, the chest radiograph reveals linear opacities in a diffuse reticulonodular pattern. The lower lung zones may be preferentially involved. High-resolution chest CT can further demonstrate a reticular pattern,

FIGURE 11-6 ■ Computed tomography of the chest in a patient with idiopathic pulmonary fibrosis. Note the reticular interstitial pattern and honeycombing at the lung bases. The patient subsequently underwent a single-lung transplant.

with honeycombing, cysts, and ground-glass opacities (Fig. 11-6).^{91,92} Mediastinal lymph node enlargement is common. BAL typically shows large numbers of neutrophils, eosinophils, or lymphocytes.^{34,35,81} Patients with high levels of lymphocytes in their BAL fluid have been shown to have a better response to steroid therapy and an improved prognosis in some studies.^{93,94} The diagnosis of IPF requires the exclusion of other known causes of interstitial lung disease, the presence of a UIP pattern on high resolution chest CT, and the presence of UIP pattern on surgical lung biopsy specimens that are consistent with high resolution chest CT findings. Hence, the principal role for lung biopsy is to exclude other etiologies of interstitial lung disease, which may alter the therapeutic plan or prognosis. Typically, a VATS or open biopsy is required because transbronchial biopsy yields inadequate tissue to make a diagnosis of IPF.^{81,95}

The mainstay of treatment for IPF is steroids or other immunosuppressive and anti-inflammatory therapies, or both, including azathioprine, methotrexate, penicillamine, colchicine, *N*-acetylcysteine (NAC), and cyclosporine. Combination therapy using prednisone, azathioprine, NAC had been recommended by international consensus committees as treatment for IPF; however, a recent randomized trial has compared the efficacy of combination therapy in patients with mild to moderate IPF to NAC alone or placebo.⁹⁶⁻⁹⁹ The combination arm of the study was prematurely terminated when interim analysis revealed combination therapy to be associated more with serious adverse events than the other arms of the trial. The NAC arm of the trial is still ongoing, but combination therapy can no longer be recommended.⁹⁶⁻⁹⁹ Novel

agents, such as pirfenidone, have also been developed to downregulate the fibrosis associated with inflammatory disorders. A recent randomized clinical trial in patients with idiopathic pulmonary fibrosis demonstrated that pirfenidone resulted in significant clinical benefit for these patients, indicating that this agent will be a mainstay of therapy in the future.^{58,59} Another phase II placebo-controlled, randomized trial examined the role of the tyrosine kinase inhibitor, nintedanib, on the progression of IPF as measured by declines in forced vital capacity (FVC), and secondary end-points of quality of life as measured by the St. George's respiratory questionnaire.^{26,100} Nintedanib is oral tyrosine kinase inhibitor that targets multiple factors including platelet-derived growth factor receptors, vascular endothelial growth factor receptors, and fibroblast growth factor receptors. These molecular pathways are involved in the development of fibrosis in animal as well as human models. The trial showed that those patients on nintedanib had a slower rate of decline in FVC and improved quality of life. As a result, two larger phase III trials evaluating nintedanib are now being conducted. Further investigation is needed to evaluate the safety and efficacy of these agents in the treatment of IPF.^{26,100}

Other medical therapies for IPF have focused on the modulating the coagulation cascade. Several animal studies have implicated the coagulation cascade in a causal role in the development of pulmonary fibrosis, and a prior clinical trial suggested a benefit to anticoagulation in patients with IPF.¹⁰⁰⁻¹⁰² However, a recent randomized trial of warfarin versus placebo in 145 patients with IPF (progressive disease) was terminated early when interim analysis demonstrated that patients taking warfarin had a worse mortality compared with placebo.¹⁰⁰⁻¹⁰² Accordingly, anticoagulation is currently not recommended.

Surgical therapies for IPF include antireflux surgery and lung transplantation. Gastrointestinal reflux disease has been shown to occur with greater frequency in those with chronic lung disease, particularly IPF.¹⁰³⁻¹⁰⁵ Consideration of antireflux surgery in this cohort is appropriate, particularly if significant reflux is detected by esophageal pH monitoring and symptom analysis despite medical therapy, because it has been suggested that surgery can improve exercise capacity, decrease oxygen requirements, and potentially delay disease progression. Patients with IPF who are undergoing antireflux surgery have variable response rates.¹⁰³⁻¹⁰⁵

Lung transplant is indicated for those patients who deteriorate despite best medical therapy.^{106,107} In general, lung transplantation is the procedure of choice for patients with IPF or other end-stage ILDs that fail medical management.^{72,108-111} The basic criteria for lung transplantation in this setting are (1) progressive dyspnea or hypoxia despite best medical therapy, (2) a predicted vital capacity of 60% to 70% or less or a predicted diffusing capacity of 50% to 60% or less, and (3) patient age of 60 years or less for double-lung transplant, or 65 years for single-lung transplant.^{112,113} Diagnosis and treatment of pulmonary fibrosis associated with connective tissue disease is similar to that for IPF.¹⁰⁸⁻¹¹⁰ However, pulmonary symptoms typically wax and wane with the disease

and often respond to treatment of the primary disease.⁸¹ Lung transplantation is indicated in those patients with stable connective tissue disease and progressive pulmonary symptoms refractory to medical therapy.¹¹³ The 5-year survival rate is only 50% to 70% after transplantation for IPF, but this is a significant improvement over the 28-month median survival reported for medically treated IPF.^{112,114,115}

Desquamative Interstitial Pneumonia

Desquamative interstitial pneumonia (DIP) tends to have a more uniform histologic appearance than IPF, and the interstitium is only mildly thickened, with a sparse infiltrate of inflammatory cells and mild fibrosis. The incidence of DIP is low, and it affects smokers usually at age 40 to 50.*

Patients exhibit dyspnea and fatigue, and the chest radiograph reveals characteristic bilateral ground-glass opacities, which may be linear depending on the degree of fibrosis. Chest CT further highlights these ground-glass abnormalities. BAL specimens typically have fewer inflammatory cells than do those from patients with IPD but relative eosinophilia.^{34,35,81,116-118} Lung biopsy, as for IPF, may be indicated to exclude other etiologies of ILD. However, the diffuse changes present throughout the lung in DIP may be seen focally in IPF, making it difficult to distinguish IPF from DIP by this means. The presence of eosinophils in the BAL fluid may aid in the diagnosis.^{117,118} DIP typically occurs in smokers, but a form of DIP in nonsmokers has also been recognized. In these patients, it may represent an extension of genetic disease with mutations in surfactant proteins as seen in the childhood form. Patients may respond to steroid therapy, but the disease is typically progressive. Ten-year survival is in the range of 60% to 70%. Lung transplantation is indicated in end-stage disease.¹¹⁶

Idiopathic Nonspecific Interstitial Pneumonia

Lung biopsy specimens from patients with idiopathic nonspecific interstitial pneumonia (NSIP) reveal a mildly thickened interstitium with an infiltrate of inflammatory cells and some fibrosis.^{71,72,74,81,119} The incidence of NSIP is rare with no sex predominance, unlike for IPF. Clinical presentation and some radiologic features of the disease are similar to those of IPF. The most common chest CT abnormalities seen in NSIP are ground-glass opacities, reticular nodularities, and traction bronchiectasis similar to other IIPs. An NSIP pathologic pattern with fibrosis and interstitial inflammation from lung biopsy specimens can occur in other settings including from drug toxicity, hypersensitivity exposures, and collagen vascular disease. It is essential to rule out these clinical scenarios prior to concluding that the disease is idiopathic. The prognosis for NSIP is variable. However, NSIP has a much better clinical response to steroid and immunosuppressive therapy and is associated with improved overall survival.^{74,81,119}

*References 50, 71, 72, 81, 86, 116.

Acute Interstitial Pneumonitis

Acute interstitial pneumonia (AIP) is rapidly progressive and clinically similar to acute lung injury and acute respiratory distress syndrome (ARDS), with the exception that there is no preceding trauma, sepsis, or known source of injury. The clinical presentation involves rapid onset with progressive dyspnea, respiratory failure, and death usually within a year. Pathologic examination of lung biopsy tissue consists of diffuse alveolar damage with a thickened fibrotic interstitium infiltrated by proliferating fibroblasts.^{72,81} In acute fulminant cases, the fibrosis can be replaced with an exudative interstitial edema similar to that found in diffuse alveolar damage, suggesting that AIP is a point on the spectrum of disease between IPF and diffuse alveolar damage. Radiologically, AIP is similar to ARDS in that chest radiographs and chest CT demonstrate characteristic bilateral patchy airspace disease and ground-glass opacities. Prognosis for those afflicted with AIP, as for those with ARDS, is poor, with a fatality rate of 70% and most patients dying within 2 weeks of diagnosis.^{81,120}

Respiratory Bronchiolitis–Associated Interstitial Lung Disease

Respiratory bronchiolitis-associated interstitial lung disease (RB-ILD) is pathologically distinct in that it is characterized by the infiltration of macrophages surrounding the distal bronchioles.¹²¹ The incidence of RB-ILD is rare, and it chiefly affects men aged 40 to 50 years. RB-ILD is strongly correlated with a history of recent or current smoking.^{81,121,122} Chest radiographs demonstrate a diffuse reticulonodular pattern. BAL fluid samples are characteristic, with abundant macrophages.^{34,35} Biopsy specimens are used essentially to distinguish the disease from eosinophilic granuloma and histiocytosis X.¹²¹ Treatment consists of steroid therapy and smoking cessation. The disease course is variable with a significant number of patients demonstrating progressive disease during treatment.

Cryptogenic Organizing Pneumonia

Cryptogenic organizing pneumonitis (COP), or idiopathic bronchiolitis obliterans organizing pneumonia, is an alveolitic pulmonary disease characterized by chronic inflammation of the alveoli, the production of granulation tissue in the bronchioles and alveoli, and the accumulation of macrophages within the alveoli.^{30,71,121,123–125} The incidence and etiology of COP is unknown, although an association with antibodies to nuclear proteins suggests an immune etiology.¹²⁶ Patients with this rare disorder have weight loss and a nonproductive cough. Chest radiographs often demonstrate bilateral diffuse opacities. Chest CT shows airspace disease with ground-glass opacities, as seen in other peribronchial processes such as RB-ILD and histiocytosis X.^{91,92} BAL fluid analysis reveals high levels of immune cells, including lymphocytes, eosinophils, macrophages, and neutrophils. However, the definitive diagnosis is dependent on lung biopsy.^{30,121,123–125} Treatment consists of steroid therapy,

with a typically rapid response and resolution of the disease. Relapses occur more often in those who have secondary forms of bronchiolitis obliterans organizing pneumonia from infection, drugs, or connective tissue disease. Relapses are also treated with steroids or other immunosuppressive regimens for longer periods, and there are reports of a minority of patients that do not respond and can progress to interstitial fibrosis.¹²⁷

Lymphocytic Interstitial Pneumonia

Lymphocytic interstitial pneumonia (LIP) is a lymphoproliferative disorder characterized by the infiltration of lymphocytes and plasma cells into the lung parenchyma.^{87,128} There is minimal to no alveolar injury. It is included, however, in the differential diagnosis of interstitial lung disease, and a lung biopsy may be required to exclude this disorder in some patients. LIP is a rare disorder seen predominantly in children, immunosuppressed patients, and women between the ages of 40 and 80 years. As with the vast majority of the ILDs discussed here, the etiology is unknown. Afflicted individuals present with the nonspecific symptoms of fever, fatigue, and weight loss. Chest radiography and chest CT illustrate a reticulonodular pattern and sporadic ground-glass opacities with some progressing to parenchymal cyst formation. BAL fluid shows a large number of lymphocytes, but lung biopsy is usually required to make the diagnosis in susceptible patient populations.^{34,35} Progression to lymphoma has been documented, but initial treatment of LIP consists of steroid therapy.^{128,129}

Idiopathic Pleuroparenchymal Fibroelastosis

Idiopathic pleuroparenchymal fibroelastosis is an extremely rare condition in which there is fibrosis of the pleura and subpleural lung tissue. Patients typically present in the fifth decade of life with recurrent infections. Pneumothorax is common given the degree of subpleural fibrosis. The disease is often progressive with a case fatality rate of 40%.^{71,130}

Unclassifiable Idiopathic Interstitial Pneumonias

In many instances, the IIP cannot be classified. In these cases, there may be inadequate or discordant clinical, radiologic, or pathologic evidence. Patients may have had prior therapies that now make identification of the underlying disease impossible. Patients should then be treated based on the most likely diagnosis.⁵⁶

Interstitial Lung Disease Associated with Connective Tissue Diseases

Connective tissue diseases (CTDs) frequently involve the lungs. CTDs such as systemic sclerosis, polymyositis/dermatomyositis, and rheumatoid arthritis most frequently have lung involvement. The majority of patients with ILD and CTD have limited or stable disease, but a significant proportion develops progressive and severe disease. Lung involvement often is an indicator of disease

severity.^{56,96} Histologic patterns seen in lung tissue biopsied include NSIP, UIP, and LIP. NSIP is the most common pattern seen in CTDs except in rheumatoid arthritis where UIP can be seen. Treatment is geared at the underlying CTD typically with immunosuppressive or immunomodulating therapy, including steroids, mycophenolate, and rituximab.^{96,131,132}

Diffuse Alveolar Hemorrhage Syndrome

Diffuse alveolar hemorrhage is a life-threatening condition that is characterized by hemoptysis from bleeding that originates from the pulmonary vasculature. Patients develop diffuse parenchymal infiltrates and hypoxemia.¹³³ The condition can be progressive and is associated with a high morbidity and mortality rate. Histologically, there is diffuse alveolar damage similar to that seen in AIP and ARDS with evidence of a pulmonary capillary leak with interstitial edema and inflammation. Diffuse alveolar hemorrhage can occur from certain medications such as amiodarone, crack cocaine, propylthiouracil, and sirolimus.¹³³⁻¹³⁵ It is also associated with various connective tissue disorders, systemic vasculitis, as well as after bone marrow transplantation. Treatment is mainly supportive with steroids and directed toward the underlying disease and hemorrhage.¹³³⁻¹³⁵ Other immunosuppressive drugs such as azathioprine or cyclophosphamide have been used with varying degrees of success in patients unresponsive to steroids.¹³³⁻¹³⁵

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM) is a rare progressive cystic disease of the lung that predominantly affects women. The disease is caused by the disorderly proliferation of smooth muscle cells throughout the lungs. Although LAM is not caused by an immune mechanism, it is listed in this section as patients with LAM have interstitial, predominantly cystic changes on their chest CT scans. Clinical features of LAM include the development of a pneumothorax, dyspnea, and cough resulting from the unrelenting cystic changes of the lung. Hence, LAM is characterized by a progressive clinical course leading to death typically within 10 to 15 years of diagnosis.¹³⁶⁻¹³⁸ Lung biopsy is required for diagnosis.

Currently, there is no standard effective medical therapy for LAM. Most therapies are supportive. New treatments are based on the discovery that individuals with LAM, much like tuberous sclerosis, have mutations in the *TSC1* and *TSC2* genes—mutations also found in tuberous sclerosis complex.^{136,139-141} The functional products of the *TSC1* and *TSC2* genes are hamartin and tuberin, respectively, which function as a cell surface associated complex regulating signal transduction through mammalian target of rapamycin (mTOR)—the target of rapamycin, the modulation of estrogen receptors, MMPs, and angiogenic factors such as vascular endothelial growth factor as well as other pathways, which are discussed further in several good reviews.^{136,140} This forms the basis of recent randomized clinical trials evaluating rapamycin as a treatment for LAM. Rapamycin targets and inhibits mTOR, which is known to be

inhibited by the hamartin-tuberin complex and whose regulation is lost in LAM.^{136,140} Doxycycline has been shown to be an inhibitor of MMPs in experimental in vitro and in vivo models, and it can be used to treat LAM.^{136,142,143} Progesterone has been used in the past with varying degrees of success to treat LAM disease progression based on the disease's predilection for women, the discovery of estrogen receptors in LAM cells, and its antiproliferative effect on LAM cells in vitro.^{144,145} Antiestrogen therapies such as tamoxifen may be useful in treating younger women.¹⁴⁶ Lung transplantation is an option for those unresponsive to therapy.

PATIENT EVALUATION

In approaching patients with suspected ILD, a thorough history and physical examination are critical (Fig. 11-7). The diagnosis may be suggested by a history of environmental or occupational exposure, connective tissue disease, or genetic disease. A similar clinical picture can be seen when intraparenchymal lymphatics are involved by malignant disease, so a history or evidence of malignancy must be sought.¹⁴⁷ Laboratory studies are performed for antibodies that suggest a connective tissue disease, for serum precipitins, or for elevated angiotensin-converting enzyme.

Pulmonary function tests are used to measure the extent of pulmonary dysfunction. ILDs are usually characterized by restrictive pulmonary physiology with a reduced total lung capacity, functional residual capacity, and residual volume. The forced expiratory volume in 1 second (FEV₁) and FVC are often decreased because of the decrease in total lung capacity. The lung's diffusing capacity for carbon

FIGURE 11-7 ■ Algorithm for the approach to a patient with interstitial lung disease. CTD, Connective tissue disease.

monoxide (DL_{CO}) is impaired because of the reduced compliance of the lung parenchyma and thus reflects the degree of resulting $\dot{V}/\dot{Q}$ mismatch more than the stage of disease. Arterial blood gases may be normal, but can reveal hypoxemia caused by significant $\dot{V}/\dot{Q}$ mismatch, particularly during exercise or sleep. Hypercarbia is usually indicative of end-stage disease. Chest imaging by plain film radiography and high-resolution chest CT is helpful in separating interstitial disease patterns from consolidative patterns and their associated diseases.¹⁴⁸ Findings on chest radiograph are often nonspecific, with bibasilar reticular markings, and may include nodular opacities, particularly in the upper lung fields in sarcoidosis, hypersensitivity pneumonitis, silicosis, berylliosis, and some of the connective tissue diseases. High-resolution chest CT provides information as to the extent and distribution of disease and is particularly useful in the investigation of early disease, when the chest radiograph may appear normal, and in the evaluation of coexisting adenopathy, malignancy, or emphysema, which have an impact on subsequent treatment. In general, the radiographic appearance may not directly correlate with the histopathologic stage of the disease or the degree of clinical impairment. However, the presence of classic radiographic findings on chest CT may be sufficient for diagnosis and thus obviate the need for tissue diagnosis in some cases.

BAL can be useful in the identification of diseases with a large inflammatory component, such as in GPA, or in the detection of a particular cellular subset, as seen in eosinophilic pneumonias or histiocytosis X (Langerhans cells), but it is nonspecific in most forms of ILD.^{34,35} Therefore, in many cases, lung biopsy by transbronchial, open, or VATS is required to make a definitive diagnosis.⁸⁴ Transbronchial biopsy is usually attempted first, particularly if sarcoidosis, Goodpasture syndrome, or eosinophilic pneumonia is a likely diagnosis, or to rule out lymphangitic carcinomatosis (Fig. 11-8) or an infectious origin. If definitive diagnosis is not possible, then surgical biopsy of two distinct disease sites, preferably on two different lobes, is warranted to provide the most effective means of establishing a diagnosis and prognosis. However, some clinicians argue that a single lung biopsy specimen from the lingual or right middle lobe has a diagnostic yield equivalent to two separate biopsies.¹⁴⁹ If adequate-size representative biopsies are obtained early in the disease course before treatment, avoiding areas of honeycombing (which reveals only nonspecific fibrosis), then the diagnostic accuracy approaches 90%.¹⁵⁰ Biopsy might not be beneficial if the clinical status or radiographic finding (e.g., extensive honeycombing) suggests that the patient is at high operative risk or that there is little benefit given the extent or prognosis of the disease.

VATS biopsy has proven to be as diagnostically accurate as open lung biopsy through a mini-thoracotomy.^{95,151} However, the patient must be able to tolerate single-lung ventilation and to remain in the full lateral decubitus position. Those who are acutely ill or are in a late stage of the disease have decreased pulmonary compliance and decreased DL_{CO} and thus a limited ability to tolerate general anesthesia, particularly with single-lung ventilation. These patients require an open lung biopsy through a mini-thoracotomy. Ideally, lung biopsies should be

FIGURE 11-8 ■ Computed tomography of the chest in a patient with a history of breast cancer and rapidly progressive bilateral ground-glass opacities. Lung biopsy revealed metastatic adenocarcinoma. There was a desmoplastic reaction around sites of tumor leading to focal areas of interstitial fibrosis as well.

attempted in patients whose disease stage is early, before diffuse fibrosis has set in, making both diagnosis and intraoperative management increasingly difficult and VATS implausible. Ideal candidates for VATS are ILD patients who are symptomatic but ambulatory with relatively preserved lung function.

More recently, there has been considerable interest in determining biomarkers for IIPs, particularly IPF. Putative serum biomarkers identified have included epithelial and macrophage proteins such as metalloproteinases such as MMP-7 or chemokine ligands (CCL-18).^{26,96,152} The goals of biomarker research are to be able to distinguish IPF from non-IPF in IIP patients as well for prognostication. It is likely that biomarkers will augment current clinical, radiologic, and histologic data for classification of IIPs in the future.

TREATMENT

Treatment is directed at the underlying condition and symptomatic relief. Hypoxemia is treated with supplemental oxygen. Unless a causative agent is identified that can be removed or specifically treated, success is low. Glucocorticoids are the cornerstone of medical therapy, and they are recommended for all symptomatic patients diagnosed with idiopathic, interstitial, eosinophilic, or cryptogenic organizing pneumonias; connective tissue disease; sarcoidosis; or ILDs. A slow taper over several months is attempted if symptoms improve, because a rapid wean can be associated with recurrent disease. Although newer therapies are being investigated, the only currently available treatment option for the significant number of patients that are medical failures is that of lung transplantation.^{73,153}

The development of techniques to treat complications of infectious lung disease formed the cornerstone of modern thoracic surgery, dominating the specialty until approximately 1960. Although advances in critical care, antibiotic therapy, and other alternative treatments have lessened the impact of many lung infections in the practice of today's cardiothoracic surgeons, current evidence suggests other categories of pulmonary infection are on the rise. There are several reasons for this change: the use of broad-spectrum antimicrobial agents, selecting out resistant organisms; the emergence of new, opportunistic organisms, freshly minted as human pathogens; the widespread application of transplant techniques, accompanied by the ubiquitous immunosuppression protocols; and importantly, the failure of preventive medicine and public hygiene measures to reduce the rate of community-acquired infection. If anything, the infectious challenges facing cardiothoracic surgeons today are more daunting than they were 40 years ago. This chapter reviews the more common causes of pulmonary infection and their treatment.

BACTERIAL LUNG INFECTIONS

Community-Acquired Pneumonia

The term *pneumonia* refers to infection of the lower respiratory tract, involving the respiratory bronchioles to the

distal alveoli. These illnesses have been subclassified based on the mode and timing of presentation and on the existing comorbidities of the affected patient. These distinctions are often useful when considering empiric antibiotic therapy. The terms *typical* and *atypical pneumonias*, which refer to the causative organism, are outdated but still occasionally useful when considering this subject. Pneumonias caused by so-called atypical organisms (including *Mycoplasma pneumoniae*, *Legionella* species, and *Chlamydia pneumoniae*) can comprise up to 40% of cases but are rarely distinguishable from typical bacterial pneumonias at clinical presentation.¹ Thus, the initial therapy chosen should consider both typical and atypical pathogens.

Community-acquired pneumonia (CAP) describes an acute bacterial or viral respiratory infection, contracted outside the confines of the hospital or long-term care facility setting.²⁻⁴ It remains a common illness, with an estimated incidence of between 5 and 6 million cases resulting in more than 1 million hospitalizations annually.^{5,6} Because CAP is not a reportable illness, these figures likely underestimate the actual magnitude of the problem. The aggregate cost for treating these patients approaches \$9 billion a year, most of which is spent on inpatient management.⁶ The length of hospitalization has been shown to be the key factor in determining the cost of treatment.⁷ Pneumonia remains the eighth leading cause of death in the United States.⁸ The mortality rate associated with the development of pneumonia ranges

Modified from Niederman MS, Mandell LA, Anzueto A, et al: Guidelines for the management of adults with community-acquired pneumonia. Diagnosis, assessment of severity, antimicrobial therapy, and prevention. *Am J Respir Crit Care Med* 163:1730–1754, 2001.

from 1% to 5% for ambulatory patients without comorbidities, to 23% in those hospitalized, and to up to 40% for those requiring intensive care unit (ICU) admission.^{8,9}

The most common pathogens responsible for CAP are listed in Table 12-1. *Streptococcus pneumoniae* has remained the most commonly identified organism, followed by *Haemophilus influenzae*, *Staphylococcus aureus*, enteric gram-negative bacilli, *Legionella* species, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and respiratory viruses.^{3,5,9} In up to 50% of cases, a causative organism is not identified. The likelihood of finding a particular pathogen often depends on the population studied (see Table 12-1) and the diagnostic tests used. For example, the use of sputum culture favors pneumococcus as the most frequently identified organism, whereas *M. pneumoniae* is seen more commonly when serologic tests are used. The presence of a “mixed” infection involving atypical and typical organisms can approach 40%,¹⁰ although it is uncertain whether the atypical organisms, when present, represent an actual coinfection, a preceding infection, or simple colonization. However, empiric antibiotic regimens that cover both typical and atypical organisms have been associated with improved survival and shorter hospitalizations in several large retrospective studies.^{11–13}

Certain risk factors may predispose patients to infection with particular organisms. For example, pneumonia caused by drug-resistant pneumococcus has been associated with advanced age (>65 years), alcoholism, immune-suppressive illness or therapy, recent β -lactam therapy, and other significant comorbidities. Enteric gram-negative infections are seen more frequently in nursing home patients; patients with significant other medical conditions, including cardiopulmonary disease; and patients who have recently undergone antibiotic therapy. Pseudomonal infections are more likely to arise in those with structural lung disease, malnutrition, or in the presence of immune-suppressive or broad-spectrum antibiotic therapy.⁵ *H. influenzae* infections occur more frequently in smokers than in nonsmokers.

Clinical Presentation of Community-Acquired Pneumonia

Patients with CAP typically present with cough (90%), dyspnea (66%), sputum production (66%), and pleuritic chest pain (50%). Nonrespiratory symptoms such as malaise, headache, nausea, myalgias, arthralgias, abdominal pain, and mental confusion are seen in 10% to 30% of patients. Older adult patients often have fewer or less severe symptoms than younger patients. Presenting signs on physical exam include fever (80%), tachypnea, tachycardia, and a generalized toxic state. Crackles on auscultation are common (80%), with indications of consolidation in up to 30% of patients.¹⁴

Evaluation with chest radiography should be undertaken in all patients who have symptoms and signs suggestive of pneumonia.¹⁵ Standard posteroanterior and lateral films classically reveal a segmental (Fig. 12-1) or lobar infiltrate, often with evidence of a parapneumonic effusion. Chest films also help distinguish pneumonia from other disorders that may display similar symptoms and can help assess the severity (e.g., multilobar involvement) of the illness. Contributing or causative factors such as bronchial obstruction, lung abscess, or tuberculosis can also be seen. The addition of computed tomography may occasionally be helpful in difficult cases, but few data are available to support its routine use in the initial evaluation of patients with CAP.

Routine collection of laboratory studies in ambulatory patients is rarely necessary but may occasionally steer clinicians toward hospital admission in equivocal cases. Laboratory studies in hospitalized patients should include complete blood count, electrolytes and glucose, renal and liver function tests, and assessment of oxygen saturation. Patients aged 15 to 54 should undergo human immunodeficiency virus (HIV) testing with informed consent.¹⁵ Tests used to identify a causative agent (including blood cultures and sputum Gram stain and culture) should be performed in all patients admitted with pneumonia, although some have questioned the usefulness of blood cultures in low-risk patients.¹⁶ Viral cultures have not

FIGURE 12-1 ■ Posteroanterior (A) and lateral (B) chest radiographs demonstrating segmental pneumonia involving the superior segment of the left lower lobe.

been shown to be useful in the initial evaluation of patients with CAP and should not be routinely performed,¹⁷ although clear improvement in the diagnostic yield has been demonstrated with the use of real-time polymerase chain reaction (PCR) analysis.¹⁸⁻²¹ Every attempt should be made to obtain these cultures before initiating therapy but not at the expense of unnecessary delays in treatment. Culture data should be correlated with the Gram stain result before narrowing antibiotic therapy. Significant pleural effusions should be tapped and sent for laboratory and culture studies. Routine serologic and cold agglutinin testing is generally not recommended in the initial evaluation of patients with CAP³ but may prove useful in select cases. This recommendation is based on the low failure rate seen with empiric therapy for patients treated in the outpatient setting. A pneumococcal urinary antigen assay approved by the U.S. Food and Drug Administration can be used to

FIGURE 12-2 ■ Posteroanterior chest radiograph demonstrating a fine interstitial pattern indicative of *Mycoplasma pneumoniae*.

augment the standard diagnostic methods,²²⁻²⁴ with the advantage of rapid results similar to the Gram stain. Sensitivity and specificity rates of 80% to 90% have been reported. Use of similar technology to detect pneumococcal antigen in sputum has also been reported.²⁵

Patients with pneumonia caused by *Mycoplasma* species often show signs and symptoms reminiscent of a mild viral illness, with a more gradual onset and less intense nature. These infections, as with other “atypical” infections, occur more frequently in younger patients. Headache, malaise, sore throat, low-grade fever, and rhinorrhea are common. Cough, when present, is frequently non-productive and spasmodic in character. Extrapulmonary manifestations may predominate, with rash, arthralgias, and neurologic abnormalities present. The physical exam of the chest may yield minimal findings, although a wheeze and crackles can sometimes be appreciated. Radiologic findings include nodular or peribronchial infiltrates, an interstitial pattern of disease (Fig. 12-2), and occasional consolidation. Pleural effusions occur frequently. Although the white cell count is often normal, anemia can be seen as a result of hemolytic anemia associated with a positive Coomb test result. Serologic diagnosis can be obtained through measurement of immunoglobulin M (IgM) or immunoglobulin G (IgG) titer using a complement fixation test.

Pneumonia caused by *Legionella* (*Legionella pneumophila*) remains problematic since the initial recognized outbreak of the disease at an American Legion convention in Philadelphia in 1976. The organism is identified in 1% to 5% of patients hospitalized with pneumonia, with considerable variation in detection as a result of geographic

patterns and difficulties in accurate diagnosis. Culture may still be the best way of identifying *Legionella*, along with a urinary antigen assay.²⁶ However, the latter test can remain positive months after the acute infection. Symptoms suggestive of pneumonia predominate (high fever, chills, dyspnea, cough), but extrapulmonary manifestations (gastrointestinal complaints, malaise, myalgias) are not uncommon. Radiographs usually reveal patchy or diffuse interstitial infiltrates and occasionally consolidation (Fig. 12-3).

Pulmonary infection with *Chlamydia* organisms such as *C. pneumoniae* present in similar fashion to other atypical pneumonias. Infection with this organism has also been associated with chronic diseases such as atherosclerotic coronary disease. Diagnostic tests used to identify this organism include direct tissue culture (sputum smear and culture are not helpful) and display of a fourfold increase in IgG titer or a IgM titer of 1:16 or higher using a microimmunofluorescence test.

FIGURE 12-3 ■ Posteroanterior (A) and lateral (B) chest radiographs demonstrating diffuse infiltrates with cavitation, radiographic features of *Legionella* infection.

Determination of Community-Acquired Pneumonia Severity

One of the key decisions made in the initial evaluation of CAP, beyond establishing a presumptive diagnosis, pertains to the need for inpatient therapy. Many of the patients afflicted with CAP are older adults with significant comorbidities for whom the progressive pulmonary infection is clearly life-threatening. On the other hand, improper admission for CAP therapy taxes the health care system billions of dollars annually. In the United States, less than 20% of patients with CAP are admitted for inpatient therapy, but these patients account for more than 90% of the costs related to the disease treatment.⁶ As a result, various guidelines have been developed to assist clinicians in the assessment of severity of illness at presentation. One such system, termed the *Pneumonia Severity Index (PSI)*, was validated with data from approximately 2300 patients in the Pneumonia Patient Outcomes Research Team (PORT) cohort study.²⁷ Based on clinical parameters obtained at initial presentation, a risk score or class is determined (Fig. 12-4). Patients with a risk class of I, II, or III had a low mortality rate (<1%) and were considered to be at low risk, thus amenable to outpatient management. Patients with a risk class of IV or V were associated with higher mortality rates (9.3 and 27.0, respectively) and were considered to be appropriate candidates for hospitalization. The value of the PSI has since been confirmed in multiple studies,²⁸⁻³³ and the PSI is endorsed within the guidelines set forth by the American Thoracic Society and Infectious Diseases Society of America.³ These guidelines emphasize a multistep process in determining the initial site of treatment, based on (1) assessment of factors that compromise the safety of home care, (2) the PSI score, and (3) clinical judgment. The PSI has been criticized, however, because of the relative complexity of the assessment required.

In contrast, the British Thoracic Society has adopted an alternative prediction rule for risk stratification in the setting of CAP, termed *CURB-65*.³⁴ The CURB-65 uses five prognostic variables: the presence of confusion, a blood urea nitrogen concentration (BUN > 20 mg/dL), respiratory rate (>30 breaths/min), low blood pressure (systolic, <90 mm Hg; diastolic, <60 mm Hg), and age (>65 years). Patients with scores of 0 or 1 were considered to be appropriate for outpatient care; those with scores of 2 or 3 should be considered for admission, perhaps to the ICU; and scores of 4 or 5 should receive mandated ICU care. A simplified version of CURB-65, termed *CRB-65*, drops the use of the BUN measurement and thus is applicable to the outpatient office setting.³⁵

The PSI and the CURB-65 have been compared in a variety of studies,^{28,36,37} with strengths and weaknesses described for both systems. The PSI is particularly good at identifying patients with a low risk of mortality, but it tends to underestimate severity of illness in some patient populations. Alternatively, the CURB-65 more accurately identifies those patients with severe CAP and at high risk of death. It has been proposed that the two assessment tools may be thought of as complementary rather than competitive tests.³⁸

FIGURE 12-4 ■ The Pneumonia Severity Index. BP, Blood pressure; O₂, oxygen; PO₂, partial pressure of oxygen.

Treatment of Community-Acquired Pneumonia

The treatment for CAP at initial presentation is outlined in Figure 12-5, as described by the American Thoracic Society and Infectious Diseases Society of America, stratified by the presence or absence of modifying factors, comorbidities, and site of initial treatment.³ Data from published reports support the use of the published guidelines, leading to better outcomes.^{11,39-46} It should be reinforced that the timing of therapy is important, with the first dose of antibiotic given 4 to 8 hours after initial presentation. Prompt administration of therapy has been associated with improved survival.⁴⁶ The use of the published guidelines facilitates prompt delivery of appropriate therapy. Furthermore, although it is desirable to narrow the spectrum of administered antibiotic agents, this is not possible in up to 50% of cases because the causative organism has not been identified. In addition, a significant proportion of cases represent mixed polymicrobial infections. The use of these guidelines using broad-spectrum therapy allows for appropriate treatment in these patients.

Clinical decisions regarding duration of therapy are poorly supported in the literature. In general, most treatment regimens last 7 to 14 days; the severity of the presenting illness, the response to therapy, and the underlying comorbidities should all be considered when addressing

duration of treatment. Most bacterial infections, including those caused by *S. pneumoniae*, are treated for 7 to 10 days provided a good clinical response is seen. *Mycoplasma*, *Chlamydia*, and *Legionella* infections should be treated for 10 to 14 days, and perhaps longer if significant comorbidity exists.

Successful response to therapy in a patient with CAP usually follows a predictable course. Stabilization of clinical parameters often occurs by 72 hours, with gradual improvement noted thereafter. The severity of the presenting illness and underlying patient disease understandably play a role in the response to therapy. The febrile response and leukocytosis typically resolve by day 4 or 5, with the radiologic findings lagging behind. In fact, the initial radiographic abnormalities may worsen before improvement is documented. Only 15% of chest films are clear at discharge, and many cases take 2 to 3 months to return to normal. With a successful response to treatment, consideration should be given to conversion to oral therapy. The American Thoracic Society describes four criteria that should be met prior to switching to oral therapy: improvement in cough and dyspnea; afebrile (<100° F) at two consecutive assessments 8 hours apart; resolving leukocytosis; and a functioning gastrointestinal tract with oral intake.⁵ Obviously, some leeway may be allowed in these criteria given the clinical situation. Compliance can be an issue with oral therapy, and consideration of drug dosing schedules and side effects

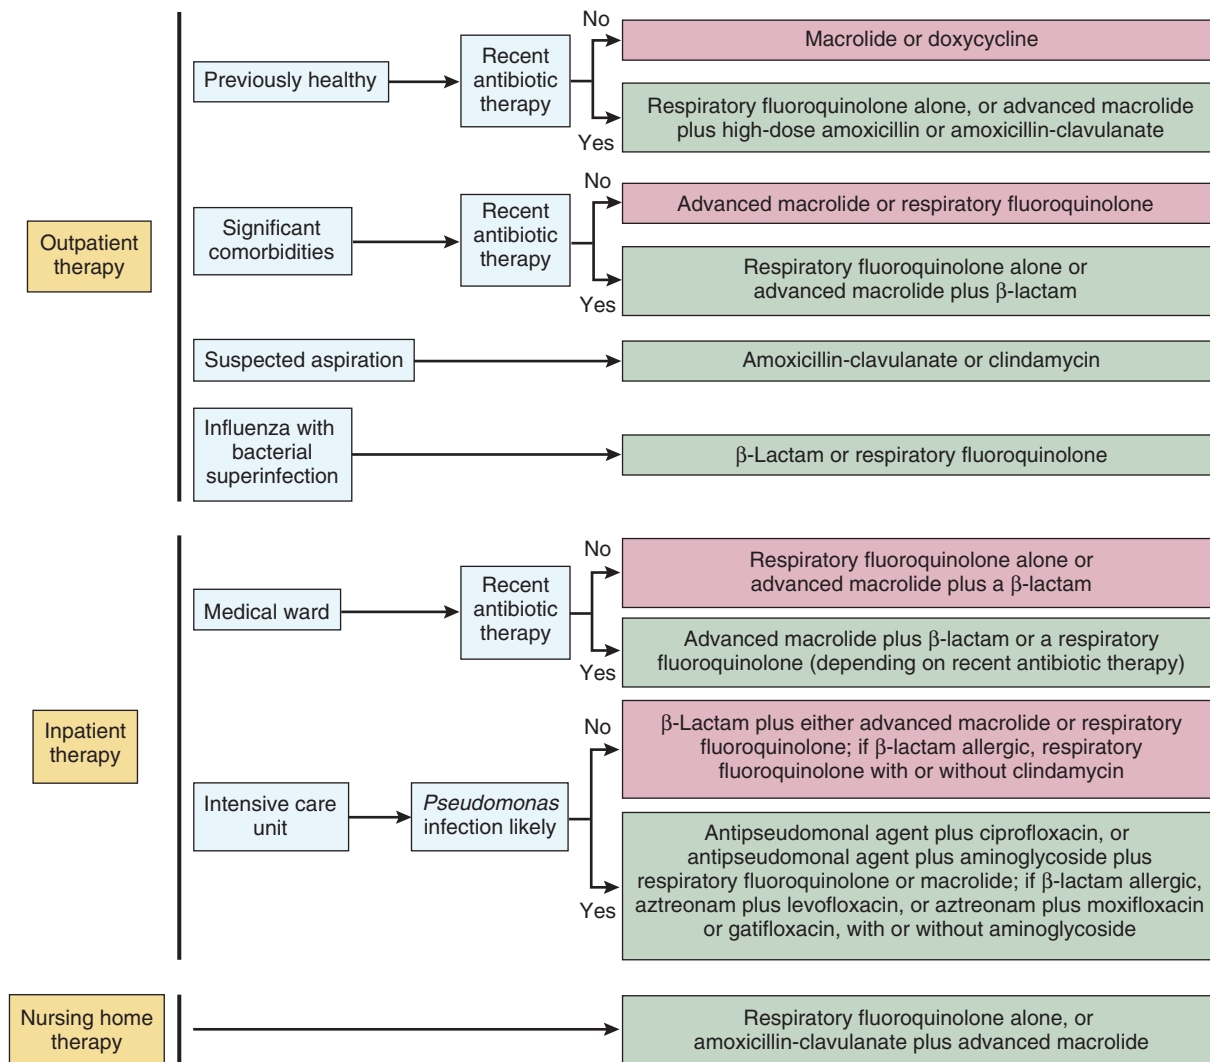

FIGURE 12-5 ■ Empiric therapy for community-acquired pneumonia.

should be taken into account when selecting an oral regimen.⁴²

Two adjunctive therapies have been studied for their effects on outcome in patients with severe CAP. In a retrospective analysis, the administration of activated protein C to a subset of patients in the PROWESS study with CAP was associated with a drop in mortality rates.⁴⁵ Further studies, including prospective randomized trials, remain pending. In at least one randomized study, the use of a continuous infusion of corticosteroids in patients with CAP was associated with lower mortality rates, shorter length of ICU stay, and shorter duration of mechanical ventilation.⁴⁷ No increase in complications was associated with the use of steroids in this patient population.

Two serum markers, C-reactive protein (CRP) and procalcitonin (PCT), have been studied to assess response to CAP therapy, determine outcome, and guide duration of therapy. Of the two, PCT seems the most promising. PCT is the precursor to calcitonin and has no hormonal effects. Serum levels of PCT rise in the setting of acute bacterial infections, stimulated by

cytokines, microbial toxins, and the cell-mediated immune response. One study determined that higher serum levels of PCT, drawn within 24 hours of admission to hospital, were associated with higher PSI levels and a greater risk of mortality.⁴⁸ Other investigators have found PCT levels useful in predicting outcome and guiding duration of therapy.⁴⁹⁻⁵¹

Clinicians should resist the urge to switch antibiotic therapy within the first 72 hours, unless marked clinical deterioration occurs. Failure to respond to initial therapy occurs in up to 10% of patients because of a variety of factors. The presence of a drug-resistant or unusual pathogen may be the cause, which may be remedied by further diagnostic tests for the causative agent, broadening the antibiotic therapy, or both. A complication of the initial pneumonia may be present, at either a local (e.g., lung abscess, empyema) or a distant (e.g., meningitis, endocarditis, septic arthritis) site. Selected imaging, such as computed tomography and echocardiography, as well as sampling of fluid collections based on these studies and physical exam, can often reveal the source of the persistent infection. Finally, several noninfectious illnesses can

mimic pneumonia and should be ruled out. This group of disease states is extensive and includes bronchogenic cancer, lymphoma, and a variety of inflammatory and interstitial lung diseases.

Hospital-Acquired (Nosocomial) Pneumonia

Hospital-acquired pneumonia (HAP) refers to pulmonary infection that occurs after at least 48 to 72 hours of admission to an acute care facility or in intubated patients. The latter situation is termed *ventilator-associated pneumonia*. HAP is the second most common nosocomial infection and has the highest mortality⁵²⁻⁵⁴, with crude mortality rates of 30% previously reported.⁵⁵ Risk factors for nosocomial pneumonia have been described and include the extremes of age, chronic lung disease, previous abdominal or thoracic surgery, endotracheal intubation, and duration of mechanical ventilation.⁵⁶

Two factors predispose patients to nosocomial pneumonia: the aerodigestive tract is colonized with bacteria, and the contaminated secretions are aspirated into the lower respiratory system.⁵⁷ Several of the preventive strategies described later are aimed at interrupting these two processes.

Ventilator-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is a nosocomial pulmonary infection that develops in patients receiving mechanical ventilation. VAP that occurs early, within 48 to 72 hours after intubation, is typically caused by bacteria responsive to antibiotic therapy (e.g., pansensitive *S. aureus*, *H. influenzae*, and *S. pneumoniae*) and frequently results from aspiration complicating the intubation process. In contrast, late-onset VAP is often caused by antibiotic-resistant organisms (e.g., methicillin-resistant *S. aureus* [MRSA], *Pseudomonas aeruginosa*, *Acinetobacter* and *Enterobacter* species).⁵⁸ Risk factors for VAP include the duration of mechanical ventilation, age older than 70 years, H₂ or antacid therapy, chronic lung disease, depressed consciousness, need for reintubation, and gastric aspiration.^{52,58-61} The incidence of VAP is significantly higher in surgical ICUs as opposed to medical ICUs, according to the Centers for Disease Control and Prevention.⁶²

There is some controversy in the literature regarding optimal diagnosis of VAP.⁶³ To date, there seems to be little evidence supporting the use of invasive (bronchoscopic) techniques for diagnosis compared with quantitative tracheobronchial aspirates, with no difference in subsequent mortality, length of hospital stay, or duration of mechanical ventilation.⁶⁴⁻⁶⁸ Bronchoscopy may be of use in patients who fail to respond to initial therapy.⁶⁹ The treatment of VAP consists of general supportive care and the administration of empiric broad-spectrum antibiotics, guided by the severity of the illness.^{52,70} The adequacy of initial antibiotic therapy appears to be the most important determinant of outcome.^{71,72} Numerous studies have examined preventive measures to limit the development of VAP. The use of semi-recumbent positioning, sucralfate instead of H₂ antagonists for stress

ulcer prophylaxis, and selective digestive tract decontamination has the strongest support in the literature.⁷³

Health Care–Associated Pneumonia

Health care–associated pneumonia (HCAP) refers to pneumonia that occurs in a nonhospitalized patient with extensive health care contacts. Examples of such contacts include outpatient intravenous therapy, hospitalization, or treatment at a hospital or dialysis unit within the past 30 days; or residence in a nursing home or other long-term care facility. In general, the recommendations for treatment mirror those suggested for HAP.⁵²

Aspiration Pneumonia

Aspiration refers to the inhalation of oropharyngeal or gastric contents into the tracheobronchial tree. This usually results in either a *pneumonitis* caused by a chemical injury from contact with sterile, acidic gastric contents or a *pneumonia* caused by inhalation of infected material. In rare cases, aspiration can lead to airway obstruction, lung abscess, and other findings. Aspiration pneumonia is a common problem, accounting for 5% to 15% of CAP, and is frequently seen in nursing home residents, in patients with swallowing disorders, and in patients with altered mental states. It is also a recognized complication of general anesthesia, occurring in approximately 1 in 3000 operations and accounting for 10% to 30% of deaths related to anesthesia.⁷⁴

The acute lung injury or pneumonitis from gastric aspiration, termed *Mendelson syndrome*,⁷⁵ appears directly related to the acidity and volume of aspirated material. In general, a pH less than 2.5 and a volume in excess of 0.3 mL/kg (approximately 21 mL in a 70-kg adult) are required to initiate lung injury. The injury follows a biphasic pattern, with the initial insult caused by direct damage of the acid on the delicate capillary and alveolar cells, followed several hours later by the rapid accumulation of inflammatory cells and mediators resulting in a local and systemic inflammatory response. Progression to acute respiratory distress syndrome and multiorgan system failure may ensue. Because the gastric contents are sterile because of the acidity, infection is usually not an initial feature in these cases but can become prominent later in the course of the illness with secondary infection of the damaged lung parenchyma. Efforts to modify the gastric pH may lead to gastric colonization with gram-negative bacteria as well as other organisms, leading to infection early following the aspiration episode. Treatment is largely supportive in nature. Particularly if the aspiration is witnessed, bronchoscopy is indicated to remove any residual fluid or debris from the airway. The use of corticosteroids in the treatment of aspiration pneumonitis has not been shown to be of benefit. Although it is common practice to initiate antibiotic therapy in these patients, this often overtreats simple pneumonitis that may resolve with supportive measures alone. Furthermore, the use of antibiotics early may encourage the development of resistant organisms. Antibiotic therapy should be considered early in patients thought to have gastric colonization and in those patients who do not

improve within 48 hours of the inciting event and who show evidence of ongoing lung injury, infection, or infiltrate.⁷⁶ Empiric coverage with broad-spectrum agents is recommended.

Aspiration pneumonia commonly arises from inhalation of colonized oropharyngeal bacteria, causing the signs, symptoms, and radiographic changes representative of pneumonia. Approximately half of normal adults aspirate while asleep,⁷⁷ and for infection to occur, the normal protective mechanisms must either fail or be overwhelmed by the volume or bacterial burden of the aspirate. In supine patients, the dependent lung segments (posterior aspects of upper lobes, superior segments of lower lobes) are affected most frequently. In upright individuals, the basilar segments, particularly on the right side, are at greatest risk of infection. The aspiration episode in patients developing pneumonia is frequently not observed, and the diagnosis is derived from the clinical picture and the characteristic radiographic changes in individuals known to be at risk. Treatment with antimicrobial therapy is appropriate. Use of antibiotics with anaerobic coverage is probably overdone but is appropriate in select cases where severe periodontal disease, alcoholism, and other disorders predominate. In hospitalized patients, coverage of gram-negative bacteria is essential.

BRONCHIECTASIS

Bronchiectasis was first described in 1819 by Laennec. It is defined by the permanent dilation of the bronchi,⁷⁸ caused by a recurrent process of transmural infection and inflammation. The disease process is characterized by the pathologic or radiographic appearance of the airways. Cylindrical or tubular bronchiectasis results in dilated, slightly tapered airways; varicose bronchiectasis resembles the chronic venous state of the same name, with areas of dilation and constriction; and in saccular or cystic bronchiectasis, progressive dilation of the airway can end in saclike, cystic structures resembling a cluster of grapes. The cylindrical changes are frequently seen with tuberculosis infections, whereas the saccular or cystic type is more common after obstruction or bacterial infection. Thick, mucoid secretions are often noted pooled in the dilated airways, causing a chronic inflammatory state involving the airway walls. The lung parenchyma distal to the dilated, ectatic airways are often damaged as well, with fibrosis and emphysematous changes present. The accompanying bronchial arteries and lymph nodes are engorged and hypertrophied as well. The left lower lobe is the area most frequently involved, followed by the lingula and right middle lobe.

The causes and disease states associated with bronchiectasis are listed in Box 12-1. The common pathway for all these disorders is recurrent, transmural infection of the bronchial wall. Bacterial infections, particularly those involving potentially necrotizing agents such as *S. aureus*, *P. aeruginosa*, *S. pneumoniae*, and various anaerobes, remain important causes of bronchiectasis, particularly when there is a delay in treatment or there are factors present to prevent eradication of the infection. Bronchiectasis in patients with allergic bronchopulmonary

aspergillosis is the result of an immune reaction to the fungal organism, with production of inflammatory mediators and subsequent direct airway invasion by the fungus. Viral infections can lead to bronchiectatic airways both through direct infection and through a reduction in host defenses. This latter theme is common when considering the pathophysiology of bronchiectasis. Primary ciliary dyskinesia and various immune deficiencies such as hypogammaglobulinemia are examples of congenital disorders in which there is impairment in host defense mechanisms. Cystic fibrosis is another important cause of bronchiectasis, with predilection for the upper lobes. Occasionally the appearance of bronchiectasis in middle age will be the presenting symptom in patients with milder forms of cystic fibrosis. Several autoimmune disorders, such as rheumatoid arthritis and inflammatory bowel disease, have been linked to the presence of recurrent pulmonary infections and the development of bronchiectasis.

Both focal and diffuse forms of bronchiectasis are seen. The focal variety is often associated with an isolated abnormality causing relative or complete bronchial obstruction. An aspirated foreign body, a slow-growing tumor, and a broncholith are examples. In rare cases, bronchial compression (as seen with middle lobe syndrome) or angulation of the bronchus (following surgical lobectomy) produce obstruction leading to recurrent infection and the development of localized disease. Bronchiectasis of postinfectious causes is more likely to be localized, whereas disease caused by congenital deficiencies is more likely to be diffuse. A recent study of stable

patients with bronchiectasis revealed a 64% incidence of colonization with what were termed *potential pathogenic microorganisms* (PPMs). The most frequently isolated PPMs were *H. influenzae*, *Pseudomonas* spp., and *S. pneumoniae*. Risk factors for PPM colonization include diagnosis of bronchiectasis before 14 years of age, an FEV₁ that is 80% predicted, and the presence of varicose or saccular bronchiectasis.⁷⁹

Patients with bronchiectasis experience recurrent pulmonary infections characterized by dyspnea and an unremitting chronic cough productive of thick, tenacious purulent sputum. Hemoptysis is common and at times can be massive because of erosion into the enlarged bronchial vessels. Occasionally patients with bronchiectasis will describe a nonproductive cough, indicative of upper lobe involvement. Auscultation reveals crackles, wheeze, or rhonchi in most patients.

The radiographic findings in bronchiectasis are understandably important in establishing the diagnosis. Standard radiographs are abnormal in most cases, demonstrating focal areas of consolidation, atelectasis, evidence of thickened bronchi (best noted as ring shadows when seen on end), and, in advanced cases, delineation of the dilated, cystic changes in the airway (Fig. 12-6). Computed tomography, particularly high-resolution imaging, is more sensitive and specific for the diagnosis of bronchiectasis. Evidence of airway dilation, changes consistent with saccules or varicosities of the airway, and lack of airway tapering toward the periphery are all consistent with bronchiectasis.⁸⁰ Upper lobe involvement suggests the diagnosis of cystic fibrosis or allergic bronchopulmonary aspergillosis, middle lobe and lingular disease is more typical of environmental mycobacterial infection such as *Mycobacterium avium* complex, and lower lobe predominance suggests bacterial involvement.

Therapy for bronchiectasis involves treatment of the underlying disorder if possible; suppression of the bacterial load through appropriate use of antibiotics; encouragement of proper pulmonary hygiene, including the routine use of bronchodilators, mucolytic agents, and postural drainage; and surgery in select cases. The role of surgery is threefold. First, patients with focal areas of

disease causing unremitting symptoms and associated with localized lung parenchymal destruction or antibiotic resistance or intolerance are candidates for resection therapy, usually via a segmentectomy or lobectomy. Most of these resections are amenable to minimally invasive techniques.⁸¹ Second, the rare patient who presents with massive hemoptysis should be considered for surgical therapy if less invasive maneuvers such as bronchial artery embolization are unsuccessful. Finally, some patients with end-stage bronchiectasis may be candidates for lung transplantation.⁸²⁻⁸⁴ As with other patients with end-stage suppurative lung disease, sequential double-lung transplantation is indicated to avoid contamination of the new transplanted lungs.

LUNG ABSCESS

A lung abscess is a circumscribed cavity within the lung parenchyma filled with purulent material and air. The cavity may form as a result of a necrotizing infection or may become secondarily infected. The abscess formation may be singular in nature or multifocal, depending on the causes. The abscess is arbitrarily termed acute if present for 6 weeks or less and chronic if it has been present for longer than 6 weeks. Further classification comes from the underlying cause, as noted earlier: a primary lung abscess arises from a necrotizing infection, whereas a secondary lung abscess forms as a result of another pathologic entity.

Box 12-2 lists the causes of lung abscess. The most common cause is inadvertent aspiration of infected oropharyngeal secretions, which can occur in the setting of impaired consciousness, in the presence of poor dental hygiene, or in association with gastroesophageal reflux

FIGURE 12-6 ■ Computed tomography scan demonstrating end-stage bronchiectasis involving the left lung, with complete parenchymal destruction.

BOX 12-2 Causes of Lung Abscess

PRIMARY

- Aspiration
 - Impaired consciousness
 - Severe periodontal disease
 - Dysphagia syndromes, esophageal reflux
- Necrotizing pneumonia
- Immunocompromised patient

SECONDARY

- Bronchial obstruction
 - Neoplasm
 - Foreign body
 - Lymphadenopathy
- Cavitating lesions
 - Neoplasm
 - Pulmonary infarct
 - Emphysema, bullous disease
- Direct extension
 - Amebiasis (liver)
 - Subphrenic abscess
- Hematogenous dissemination

disease or various dysphagia syndromes (strictures, Zenker and other diverticula, dysmotility disorders, achalasia, and others). A lung abscess can occur as a sequela of necrotizing lung infections, particularly in the setting of an immunocompromised host. Bronchial obstruction, caused by tumor, foreign body, or external compression of the bronchus, can predispose to distal lung infection and subsequent abscess formation. A preexisting cavity within the lung parenchyma, as a result of a cavitating neoplasm, a resolving infarct, or even structural lung disease, can lead to secondary infection and abscess. Direct extension of an adjacent abscess can occur. Finally, hematogenous seeding from another source can produce abscesses within the lung, often multifocal. Recognition of the secondary nature of the abscess can have direct therapeutic implications—for example, an abscess resulting from a foreign body aspiration will likely respond poorly to treatment if the offending item is not removed.

The location of lung abscesses is determined by the segmental anatomy of the tracheobronchial tree and the underlying cause. Because aspiration is a major cause, the dependent segments—the posterior segment of the right upper lobe and the superior segments of both lower lobes—tend to be involved frequently. The distribution roughly falls into right upper lobe, 25%; right middle lobe, 10%; right lower lobe, 33%; left upper lobe, 12%; and left lower lobe, 20%.⁸⁵

The bacteriology of lung abscesses frequently falls in line with the underlying cause. Many ambulatory patients with lung abscess have gram-positive bacteria (e.g., alpha- and beta-hemolytic streptococcus, *S. aureus*, *S. pneumoniae*, *Streptococcus viridans*) as the source, whereas gram-negative organisms (e.g., *Proteus* spp., *Escherichia coli*, *P. aeruginosa*, *Enterobacter* spp., and *Eikenella* spp.) predominate in nosocomial infections. In lung abscess caused by aspiration, mixed flora are often present and anaerobes play an important part.⁸⁶ Aerobic gram-positive cocci and facultative gram-negative bacilli are commonly found, including *S. aureus*, *Streptococcus pyogenes*, *Klebsiella pneumoniae*, and *P. aeruginosa*.

Clinically, patients complain of cough, fever, malaise, weight loss, dyspnea, and occasionally pleuritic chest pain. The symptoms are reminiscent of pneumonia and may be insidious in onset. Hemoptysis may be a complicating factor in rare cases and can vary from blood streaks in the sputum to life-threatening hemorrhage. With cavitation and drainage into the tracheobronchial tree, patients will likely describe production of large volumes of foul-smelling sputum. The uninvolved lung can become soiled through a spillover effect and produce respiratory failure. If large enough, the abscess can exert a mass effect on adjacent structures. Rupture into the pleural space is uncommon but can lead to empyema and fulminant sepsis.

A chest radiograph is likely to show a cavitary space within the lung, accompanied by an air-fluid level (Fig. 12-7). In contrast with a hydropneumothorax, the abscesses are more likely to have equal air-fluid levels on both posteroanterior and lateral films.⁸⁷ Features of a lung abscess may be difficult to appreciate on plain film exam and can be mistaken for alternative diagnoses. Computed tomography is helpful in these cases,

FIGURE 12-7 ■ Posteroanterior chest radiograph demonstrating a lung abscess with air-fluid level.

delineating the exact anatomic features and location of the abscess and its relation to adjacent structures. For example, a cavitary neoplasm may be confused with an abscess. Compared with the thin, smooth walls of the abscess, cavitation secondary to tumor is usually associated with thick, irregular walls, features that do not respond to antibiotic therapy. An interlobar fluid collection or empyema may also be mistaken for a lung abscess. A lenticular shape, obtuse angle with the chest wall, compression of neighboring bronchovascular structures, and a “split pleura” sign signify the presence of pleural fluid in these cases.⁸⁸ In addition to standard laboratory investigation, bronchoscopy should be used to assess for bronchial obstruction caused by tumor or a foreign body and possibly to obtain cultures. Accurate culture data may be best obtained through percutaneous fine-needle aspiration. In a series reported by Yang and colleagues,⁸⁹ fine-needle aspiration yielded a 94% success rate in culturing pathogens, compared with 11% from sputum culture and only 3% from lavage. Attempted drainage via bronchoscopic means should be discouraged in most cases because of the risk of flooding the airways with purulent material.

The successful treatment of lung abscess involves prolonged antimicrobial therapy targeted at the causative organism combined with establishment of adequate drainage. In most cases, the drainage can be accomplished internally, aided by postural techniques and chest physiotherapy. If internal drainage is inadequate, percutaneous drainage may be done, usually with an excellent response (Fig. 12-8). The complications of percutaneous drainage (empyema, pneumothorax, hemothorax) occur in less than 10% of cases, even less so if pleural symphysis is present. The course of antibiotic therapy typically lasts 6 to 8 weeks, with radiographic resolution occurring by 4 to 5 months. Medical therapy for lung abscess is generally successful in 85% to 90% of cases.⁹⁰ Indications for surgical intervention would include empyema, development of a bronchopleural fistula, significant

FIGURE 12-8 ■ Computed tomography scan and chest radiographs demonstrating a large lung abscess (*upper panels*) with resolution after appropriate percutaneous drainage (*lower panels*). The arrow depicts the collapsed, contracted abscess cavity.

hemoptysis, persistence of the abscess despite adequate therapy, and suspicion of underlying malignancy. During surgical procedures for lung abscess, special attention should be paid to protecting the contralateral lung from spillage, usually through the use of a double-lumen tube. Resection of the involved segment of lung is usually performed, although in cases of rupture into the pleural space, simple unroofing of the cavity, decortication, and wide drainage will usually suffice. Some success with endoscopic drainage of lung abscesses has been reported.⁹¹

PULMONARY MYCOBACTERIAL DISEASE

Mycobacterial pulmonary diseases include infections with *Mycobacterium tuberculosis* and its more virulent forms, multidrug-resistant tuberculosis (MDR-TB) and extensively drug-resistant tuberculosis (XDR-TB).⁹² Other mycobacterial infections caused by organisms have gone through a series of name changes, including atypical mycobacteria, mycobacterium other than tuberculosis, environmental mycobacterial infections, and the most commonly used term, nontuberculous mycobacteria (NTM).⁹³ Whereas good epidemiology studies can be found for tuberculosis infections as well as MDR-TB/XDR-TB, there are poor epidemiology data for NTM infections. This is probably because NTM infections are not transferable from person to person and thus are not reportable to local or national health authorities.

In 2013, there were 9 million patients worldwide who developed tuberculosis, and 1.5 million patients died of the disease.⁹⁴ Unfortunately, most of these cases are in countries where health care systems are in dire need of help. In India, approximately 500,000 people die from tuberculosis yearly. Fortunately, only 10% to 15% of those exposed to the tuberculosis organism acquire the clinical disease; however, this leaves a large number of individuals who make up a latent source for later activation with tuberculosis if their resistance breaks down as a result of disease or aging.

The early treatment of tuberculosis gave rise to the sanatoria system. It was believed that rest and fresh air were beneficial in the treatment of tuberculosis. However, it has never been well documented that this form of therapy produced any long-term benefit.

Surgery for tuberculosis began with collapse therapy. The tuberculosis organism is an obligate aerobe, and it was reasoned that preventing oxygen from entering the cavities would be beneficial in the treatment of patients with cavitary pulmonary tuberculosis. Various forms of collapse therapy have been used, including thoracoplasty, wax or Lucite ball plombage, phrenic nerve crush or interruption, pneumoperitoneum, and induced pneumothorax. Collapse therapy continued to be the treatment of choice for tuberculosis infections until chemotherapy with streptomycin and para-aminosalicylic acid (PAS) was introduced in 1945. It was not until the introduction of isoniazid in 1952 that prolonged cures could be obtained with antibiotic therapy.

Resectional surgery gradually replaced collapse therapy as the primary surgical approach to patients with tuberculosis infections having residual destroyed lung or cavitory disease. With the introduction of rifampin in 1966, the need for surgery was markedly reduced and the sanatoria system gradually became extinct. Drug-sensitive tuberculosis in almost all cases can be cured with antibiotic therapy alone. It is hoped that recent advances in diagnostic testing, including point-of-care recognition using Xpert MTB/RIF (a real-time PCR assay), will aid in identification of infected individuals and initiation of therapy.⁹⁵⁻⁹⁷ The standard treatment of drug-sensitive tuberculosis is 6 to 9 months of isoniazid and rifampin, adding pyrazinamide and ethambutol during the initial 2 months.^{98,99} Patients with drug-sensitive tuberculosis who are treated appropriately are only operated on for complications such as bronchostenosis, massive hemoptysis (>600 mL in 24 hours), bronchopleural fistula, to rule out the presence of cancer, and occasionally decortication of a trapped lung, which occurs when polymicrobial contamination occurs within the pleural cavity in tuberculosis patients who have had a pleural effusion.

Patients with tuberculosis whose organism is resistant to both isoniazid and rifampin are classified as having MDR-TB. XDR-TB strains are resistant not only to isoniazid and rifampin but also to fluoroquinolones and either aminoglycosides (amikacin, kanamycin) or capreomycin or both.^{100,101} These patients with MDR-TB/XDR-TB present a much greater challenge to clinicians, who must use four to five drugs to optimize treatment success.¹⁰¹⁻¹⁰³ Recent approval of new drugs, such as bedaquiline and delamanid, provide new hope in the medical treatment of drug-resistant tuberculosis.^{104,105}

Surgery plays a greater role in the management of drug-resistant tuberculosis. In addition to the previously listed indications for surgery, patients are also operated on for persistent cavitory disease, destroyed lobe, or destroyed lung with or without a positive sputum. In the United States, patients with MDR-TB make up the largest group of patients operated on for pulmonary infections with tuberculosis.¹⁰⁶ The addition of surgery to the treatment regimen has been shown to be beneficial.^{107,108}

Patients with nontuberculous mycobacterial infections (NTMs) present a different challenge. The most common NTM infection is that of the *Mycobacterium avium* complex. This includes both *Mycobacterium avium* and

Mycobacterium intracellulare, which are almost indistinguishable from each other on culture. Infections with the so-called rapid growers, such as *Mycobacterium chelonae*, *Mycobacterium abscessus*, and *Mycobacterium fortuitum*, seem to be increasing in the United States although accurate epidemiology is not available. These infections are more difficult to treat because good antibiotic coverage is not available.¹⁰⁹ Some of these rapid grower infections are extremely virulent and can destroy an entire lung (Figs. 12-9 and 12-10), and surgery, along with continued use of any antibiotics available, offers the only hope to control the process. Specific types of NTM infection include infection of the middle lobe and lingula of women (Fig. 12-11).¹¹⁰ This usually occurs in slender women with little or no body fat and is associated frequently with skeletal abnormalities such as scoliosis or pectus excavatum.¹¹¹ This syndrome has not been found in men, in our experience; however, if it does occur, it is extremely rare.

Preparation for surgery is an important part of the therapeutic approach for patients with mycobacterial infections. The most important aspect of preparation is nutrition. Patients with an albumin concentration below 3.0 g/dL are not operated on. Nutritional supplementation is accomplished either orally or by gastrostomy or jejunostomy feeding tubes to improve the patient's anabolic state prior to surgery. The best available antibiotic

FIGURE 12-9 ■ Computed tomography scan showing severe cavitory disease in a patient with *Mycobacterium chelonae* infection.

FIGURE 12-10 ■ Perfusion scan of the patient depicted in Figure 12-9, demonstrating absence of perfusion to the left lung.

FIGURE 12-11 ■ Computed tomography scan of a woman with *Mycobacterium avium* complex infection of the right middle lobe and lingula.

therapy is given for approximately 3 months prior to surgery. This can be prolonged if bacterial counts are decreasing and can be shortened if the sputum becomes negative for acid-fast bacilli. Approximately 50% of patients with MDR-TB have negative sputum prior to surgery. Routine evaluation, as with other pulmonary surgery, includes pulmonary function tests, ventilation perfusion scans, and computed tomography.

Surgical principles include leaving enough viable lung tissue to have a functional postoperative patient. Double-lumen tubes or bronchial blockers are used in all operations. All grossly involved lung, which includes cavitory disease and destroyed lung should be removed, whereas nodular disease remaining in other parts of the lung can be left behind. The use of muscle flaps is controversial. However, it is our opinion that using muscle flaps to fill space following lobectomies is often helpful. With muscle flaps, we think that the incidence of bronchopleural fistula has been decreased. Muscle flaps are used after pneumonectomy if there is a polymicrobial contamination, significant drug resistance, or positive sputum at the time of surgery. If there is massive contamination, the chest is left open and an omental flap is used. Omental flaps are also used to cover the bronchus in the absence of any muscle as a result of previous surgery or extreme cachexia. If the chest is left open (Eloesser procedure), it is packed with quarter-strength Dakin solution using Kerlix gauze and changed on a daily basis for 5 to 6 weeks. When the opening is closed, assuming the intrathoracic chest wall is clean, Clagett solution is left in the pleural cavity. Pleural tents have been suggested to help eliminate space and seal air leaks. This is not practical in mycobacterial surgery because most of the dissections over the upper lobe are done in the extrapleural plane. The latissimus dorsi muscle is used whenever significant space problems are expected after lobectomy, and it is also used to cover the bronchus and hilum. If only bronchial support is needed following a pneumonectomy, intercostal muscle can be used. Appropriate antibiotic

therapy is continued for at least 12 months following culture conversion.

Whereas tuberculosis infections can infect normal lung tissue, NTM infections most frequently affect previously diseased lungs and have a much more indolent course than does tuberculosis or MDR-TB. Lung damage can result from previous infections such as tuberculosis, bronchiectasis, or chest wall irradiation. NTM patients often are found to have genetic abnormalities such as heterozygous cystic fibrosis, α_1 -antitrypsin deficiency, or cilia dysfunction. It is also of note that over 50% of the patients with NTM infections have esophageal dysfunction. These patients often reflux at night, causing contamination and damage to the lungs and making them more susceptible to pulmonary disease.

In the United States, there is an abnormally high number of patients with NTM disease that are Caucasian. In addition, the overwhelming majority of NTM patients are women (relative to men). The reasons for these two findings are still not clear.

Operative mortality in experienced hands should be less than 3%. The largest study to date involving anatomic lung resection for NTM disease reported a mortality rate of 2.6% in 236 consecutive patients, with no deaths in the second half of the series.¹¹² Complications following mycobacterial surgery are high—in the 25% to 30% range—but with experience, this can be brought down to less than 15%. Specific complications include a high rate of bronchopleural fistula, most often occurring after right pneumonectomy for NTM infections. Wound infection after *M. chelonae* and *M. abscessus* is common, and careful attention to wound closure is necessary. Other complications, such as air leaks, bleeding, and postpneumonectomy pulmonary edema, are similar to those of other thoracic procedures for nonmycobacterial disease.

Results of surgery for tuberculosis or MDR-TB are gratifying, whereas surgery for NTM infections is less successful because of the long duration of indolent disease prior to surgical intervention. Earlier surgery in these patients should improve the results. Persistence in aggressively treating surgical complications is often necessary to obtain good results and requires dedicated thoracic surgeons experienced in these difficult cases.

With 33% to 40% of the world infected with tuberculosis and with the presence of poverty, this disease will not go away. With the increasing number of NTM infections, at least in the United States, surgery will continue to play a role in the therapy of these patients.

MAJOR PULMONARY MYCOTIC INFECTIONS

Of more than 100,000 species of fungi, only 300 or so are associated with pulmonary disease. Fungal infection of the lung results from inhalation of the infectious agent. Colonization or asymptomatic fungal infection is common in the United States: an estimated 30 million are infected with *Histoplasma capsulatum* and another 10 million with *Coccidioides immitis*. Serious infection is rare but is seen with increasing frequency in immunocompromised populations. The increasingly advanced use of chemotherapy

for neoplasms, antibiotics for infections, immunosuppressive therapies for organ transplantation, and corticosteroids for various conditions has increased opportunistic infections by usually harmless saprophytes such as *Aspergillus*, *Candida*, and *Mucor*. Under these conditions, the formerly clear differentiation between so-called pathogenic and nonpathogenic fungi has become blurred.

In addition to detailing the medical conditions that predispose to infection, other areas of the patient history can yield important clues to the causative agent. The three major fungal infections seen in healthy populations—histoplasmosis, coccidioidomycosis, and blastomycosis—are recognized as endemic organisms in specific geographic areas of the United States. These organisms are dimorphic; they exist in nature as a mycelium (mold) that bears infectious spores, which later enter the host and develop into a yeast-like phase that is the tissue pathogen. These morphologic differences occur in response to changes in temperature. The spores invade the host through an aerosolized form via the respiratory tract, resulting in a mild or asymptomatic infection. Chronic pulmonary or disseminated infection is uncommon, with the presence of an intact cell-mediated immune response critical to preventing serious illness. The more common opportunistic fungi—*Aspergillus*, *Cryptococcus*, *Mucor*—are ubiquitous and are located in the soil. Proximity to building or construction sites where aerosolization of these organisms can occur has been linked to an increased incidence of *Aspergillus*, *Histoplasmosis*, *Coccidioidomycosis*, and other infections.^{113,114}

Fungal infection of the lung is best established by recovery of the infecting organism by culture, but recognition in smears or tissue sections may be enough for diagnosis. The best two stains for demonstration of fungi in tissue are periodic acid–Schiff and methenamine silver, but no one stain demonstrates all organisms. Specific immunologic changes in the host response may provide a strong indication of the diagnosis and may often lead to therapy before actual isolation of the organism can be achieved.¹¹⁵ All too often, however, it is not possible to find pathognomonic organisms in the stained specimens and only a presumptive diagnosis can be made. Cultures of fungi can be made from tissues, sputum, pleural fluid, and other clinical specimens. Induced sputum samples, obtained in the morning and at least six in number, are recommended.¹¹⁵ Sabouraud's dextrose agar is an excellent general-purpose culture medium. Prompt delivery of the specimens to the laboratory is essential. Because respiratory tract cultures may simply be the result of fungal colonization, the culture isolates from these sites, which are not sterile, may not correspond to infection. However, risk stratification of the host may aid in this matter. One study demonstrated a positive culture for *Aspergillus* in immunocompromised patients such as bone marrow transplant recipients was associated with invasive infection 50% to 70% of the time, whereas a positive culture in cystic fibrosis patients was rarely combined with invasive aspergillosis.¹¹⁶ Serologic tests for circulating fungal antigens (such as galactomannan in aspergillosis) and circulating antibodies to fungal antigen (histoplasmosis and coccidioidomycosis) can aid in diagnosis. Molecular diagnostic techniques using PCR

technology are being developed for *Aspergillus*, *Candida*, and *Cryptococcus*.^{117,118}

Histoplasmosis

Histoplasmosis is a fungal infection caused by the dimorphic fungus *Histoplasma capsulatum*, which exists in mycelial form in the soil (its natural habitat) and in yeast form at body temperature. It is endemic in the Mississippi and Ohio river valleys, where the incidence of positive skin reactions to the fungus exceeds 80%.¹¹⁹ Furthermore, the incidence of skin test reactivity probably underestimates the true incidence, because the skin test may revert to negative over a period of time.

The yeast phase of the organism is not contagious, and there is no danger of transmission through direct human contact. The microspores from the mycelial phase act as the transmitted agent, inhaled into the distal air spaces in the lung. The critical inoculum is unknown. Within days, the microspores germinate into yeast spores, attracting neutrophils and macrophages to the site of infection. Neutrophils are largely ineffective against the yeast spores, which are ingested by the macrophages. Infected macrophages transport the spores to other areas in the reticuloendothelial system, producing a subclinical disseminated infection. This process is poorly controlled in those with impaired T cell immunity. The outcome of infection is determined by the development of a specific cell-mediated immune reaction within approximately 2 weeks. Granulomas form within the lungs and mediastinal lymph nodes to wall off residual organisms. As the epithelial cell granulomas age, caseating necrosis develops in the central areas and may calcify as the peripheral portions become fibrotic. Within these lesions, *H. capsulatum* organisms are usually found only in the caseous material, seen well with methenamine silver stain. The yeast are often found intracellularly in macrophages.

Approximately half of the cases of acute pulmonary histoplasmosis are asymptomatic. The remaining patients have a flu-like illness with chills, myalgias, headache, nonproductive cough, dyspnea, and pleuritic chest pain. The disease is self-limited, usually lasting a week or two, but frequently with fatigue lasting for several weeks. Occasionally patients will be troubled by pericarditis or persistent symptoms or arthralgia and erythema nodosum.¹²⁰ These symptoms respond well to nonsteroidal anti-inflammatory agents.

Progressive disseminated histoplasmosis develops rarely, usually seen in those with impaired cell-mediated immunity. The liver, spleen, lymphatic system, bone marrow, and adrenal glands are most frequently involved. Diffuse pulmonary infiltrates may appear and progress rapidly, at times accompanied by shock and disseminated intravascular coagulation.

Chronic cavitary pulmonary histoplasmosis occurs in approximately 10% of patients with symptomatic histoplasmosis. Most have chronic obstructive pulmonary disease (COPD) and other structural defects in the lungs, which predispose them to the illness. Clinically, the disease is similar to cavitary tuberculosis, except that the illness is less severe. The radiographic picture mimics that seen in tuberculosis, with fibronodular changes,

often involving both pulmonary apices, cavities, and adjacent pulmonary pleural thickening.

Fibrosing mediastinitis represents excessive scarring from prior histoplasmosis infection. The symptoms are produced by gradual, relentless compression of mediastinal structures, including the superior vena cava, pulmonary vessels, esophagus, and tracheobronchial tree. The calcified nodes may actually erode into the latter two structures, presenting as a broncholith with airway obstruction and hemoptysis or with a localized esophageal leak and dysphagia (Fig. 12-12). The progression is fatal in 10% to 20% of cases, and attempts to surgically bypass or remove the obstructing lesions are difficult and often unrewarding. Antifungal and steroid therapies are of limited use in fibrosing mediastinitis and do not slow the progression of the disease.¹²¹

Histoplasmoses are the residua of healed primary histoplasmosis and are usually seen as asymptomatic coin lesions on routine chest films. Their significance lies in the fact that the lesions, if uncalcified, may be impossible to differentiate from neoplasm, and surgical excision may be indicated. Computed tomography may reveal central calcification or peripheral calcification with a “target” appearance indicating a benign diagnosis.

Definitive diagnosis of active histoplasmosis relies on isolation of the fungus in culture. Serologic immunodiffusion tests detect antibodies to *H. capsulatum* in 24 to 48 hours but may also be positive in those with a remote history of the disease. Furthermore, the test is negative in up to 10% of patients with culture-proven histoplasmosis, usually in immunocompromised patients.

Amphotericin B is the mainstay of significant histoplasmosis infections.¹²² The primary, self-limiting

infection does not require therapy unless progression to severe illness is documented. Treatment is always indicated in the disseminated form of the disease and in immunocompromised populations. Chronic pulmonary histoplasmosis may alternatively be treated with ketoconazole or itraconazole. Surgical intervention in the chronic form of the disease is indicated only if the thick-walled cavities fail to respond to an adequate course of antimicrobial therapy and if pulmonary function permits.

Coccidioidomycosis

Coccidioidomycosis is the illness caused by the pathogenic fungus *Coccidioides immitis*. This dimorphic fungus is found in the soil as a mold and in tissues as an endospore. Relatively hardy, it can withstand periods of high salinity and drought but is intolerant of freezing temperatures. It is endemic in the desert southwest United States, and protection from infection in the endemic area is almost impossible. The infecting structures are termed *arthroconidia*, which are separated from the mold stalk by wind or other disturbances. The arthroconidia are transported through the air, resulting in inhalation into the distal air sacs of the lung and transformation into spherules. The spherules enlarge in the lung and become packed with endospores, which ultimately rupture, liberating the tiny endospores and perpetuating the invasive process. The severity of the clinical course after inhalation of the endospores is determined mainly by the host's ability to develop cell-mediated immunity against *C. immitis* to control infection. Children exposed are more likely to develop a mild or asymptomatic infection, whereas adults are more likely to have a severe

FIGURE 12-12 ■ Computed tomography, contrast esophagography, and chest radiography demonstrating calcified mediastinal granulomatous disease secondary to histoplasmosis, with erosion into the adjacent esophagus.

primary infection with dissemination. African Americans are 12 times more likely to develop disseminated disease than Caucasians, with American Indian, Hispanic, and Filipino ethnic groups also at increased risk.¹²³ Men are at higher risk than women.

The most common clinical manifestations of primary pulmonary coccidioidomycosis, commonly referred to as *desert fever* or *valley fever*, are cough, fever, fatigue, dyspnea, chest pain, and headache. The symptoms develop 1 to 4 weeks after exposure. Approximately 20% of patients will have erythema nodosum or erythema multiforme, indicating an excellent cell-mediated immune response and prognosis. In most cases, the disease is self-limiting and remits in a few days. More severe primary infections can be accompanied by high fever, cough, weight loss, and development of pulmonary infiltrates and may take weeks to resolve. If the symptoms persist for more than 6 weeks with concomitant radiologic findings, treatment is usually started.

Patchy infiltrates are the most common radiographic finding in primary coccidioidomycosis, which range in size from subsegmental to lobar. Infiltrates may be single or multiple. Adenopathy can be present and be so dramatic as to resemble lymphoma. Subsequent necrosis of the infiltrate commonly occurs, resulting in cavitation or coalescence into a granulomatous nodule (Fig. 12-13). The cavities are usually peripheral in location and may rupture into the pleural space, causing a pleural effusion, pneumothorax, bronchopleural fistula, and empyema. Secondary infection of the cavity and hemoptysis may also occur. The nodules that form within the lung parenchyma mimic bronchogenic carcinoma and often require resection to settle the issue.

Disseminated coccidioidomycosis may occur, typically as the result of hematogenous spread. The symptoms are insidious in onset several weeks after the primary infection. Skin and soft tissue lesions, bone and joint lesions, involvement of the genitourinary system, and meningitis can result.

The diagnosis of coccidioidomycosis depends on the identification of *C. immitis* within the body tissues or

fluids. Detection by culture may take several weeks. Serum or cerebrospinal fluid can be tested to detect antibodies to *C. immitis*, through an immunodiffusion method. This test usually becomes positive within 4 weeks after an initial infection and remains positive throughout the clinically active illness. Some individuals continue to produce detectable antibodies for up to 1 year after recovery. Negative serology does not exclude a diagnosis of coccidioidomycosis. A skin test is available that shows a reaction to coccidioidin, prepared from the mycelial phase of the organism. A positive test is highly correlated with protection and a favorable prognosis. Patients with disseminated disease often lose this measure of cell-mediated immunity, and a persistently negative skin test at the end of therapy suggests the possibility of relapse.

Most patients with coccidioidomycosis require no therapy. All patients with disseminated disease and those with extensive pulmonary disease should be treated. Amphotericin B is the treatment of choice in severe disease, with lesser forms treated with fluconazole or itraconazole.¹²² Meningeal involvement is treated with intrathecal therapy. Surgical intervention is indicated for resection of old granulomas suggestive of carcinoma and for complications arising from cavitary disease.

Blastomycosis

Blastomycosis is a systemic mycotic infection caused by the dimorphic fungus *Blastomyces dermatitidis*. The fungus is a soil-dwelling organism endemic to the southeastern and central United States, although interestingly it has been cultured from soil only infrequently.¹²⁴ This fact, as well as the lack of a suitable skin test, has made precise definition of the endemic region problematic. The infecting microconidia are inhaled to the level of the alveolus, where the organism converts to its parasitic yeast-like form. The yeast multiplies rapidly, attracting neutrophils and macrophages and, later, a T cell-mediated immune reaction. An area of pneumonitis forms, with involvement of the regional lymph nodes. As granuloma formation finally occurs, with the organisms walled off, healing begins with "rounding off" of the infiltrate and fibrosis. These produce the late coin lesions suggestive of carcinoma. Late calcification of these lesions is less common than with histoplasmosis or coccidioidomycosis. If delayed hypersensitivity does not develop, the fungus may disseminate throughout the body and involve the skin, bones, meninges, and prostate or adrenal glands, producing disseminated disease. In patients with cell-mediated immune deficiencies, blastomycosis can present as a rapidly progressive infection.¹²⁵

The primary infection site is the lung, although the incidence of asymptomatic infection is difficult to determine. In symptomatic cases, the disease may present acutely with fever, chills, myalgias, arthralgias, and a dry, hacking cough that becomes productive. Hemoptysis and pleuritic pain can occur. Most symptomatic patients recover within 2 to 3 weeks. Occasionally the symptoms will persist, resulting in chronic suppuration and cavitation. Patients who seem to have recovered may develop recurrent infection in areas remote from the primary site.

FIGURE 12-13 ■ Computed tomography scan demonstrating a granuloma in the lingula caused by coccidioidomycosis.

Radiologic findings are variable. Single or multiple sites of infiltrate or nodularity can occur, often with a lower lobe predilection. Pleural involvement may be seen, including thick, irregular pleural-based lesions.

B. dermatitidis is readily isolated from infected fluid or tissue if proper care is given in the specimen processing. This round, thick-walled, single budding yeast measuring 8 to 15 μm in diameter may be seen reasonably well with routine hematoxylin and eosin stains, although periodic acid–Schiff and methenamine silver stains usually have many more organisms. Sputum or other fluids should be prepared with a 10% potassium hydroxide solution and examined under a microscope with reduced illumination. A definitive diagnosis may be obtained within an hour. Identification by culture, in contrast, can take weeks. Serodiagnosis of blastomycosis has not been successful to date.

For subclinical disease, treatment may be deferred. In more severe but not life-threatening forms of the illness, itraconazole is used preferentially.¹²² Itraconazole may also be used as an adjunct following therapy with amphotericin B in disseminated cases, those with immune compromise, and in those with mild extrapulmonary disease. For life-threatening and diffuse disease, amphotericin B is the drug of choice.¹²² Meningeal involvement also mandates amphotericin B therapy. The role of surgery in blastomycosis is to help with diagnosis and rule out malignancy.

Aspergillosis

Aspergillus is a ubiquitous soil-dwelling organism that releases small conidiophores that are easily inhaled (Fig. 12-14). It is inevitable that exposure occurs, and thus the development of active infection depends on other influences. Although more than 200 species of *Aspergillus* are known, only a few are thought to be pathogenic for humans. *Aspergillus fumigatus*, *Aspergillus flavus*, and *Aspergillus niger* are the most common, with *A. fumigatus* dominating in human disease. In patients with normal immune function, no chronic or structural lung disease, and no hypersensitivity or allergic concerns, an infection is usually averted. In others, three main types of *Aspergillus* infection may occur, with considerable overlap. Patients may develop a noninvasive aspergilloma, invasive aspergillosis, or a hypersensitivity reaction to *Aspergillus*, causing illness. The spectrum of *Aspergillus* infection is detailed in Figure 12-15.

Aspergilloma

Individuals with cavitary lung disease may develop an aspergilloma, a noninvasive infection characterized by a mass of fungal mycelia, inflammatory cells, mucus, and tissue debris, all within a preformed lung cavity (Fig. 12-16). The cavity classically has been attributed to a prior tubercular infection, although this is obviously not always the case. Other types of fungus may produce a fungal ball, yet *Aspergillus* is by far the most common.¹²⁶ The true incidence of aspergilloma is unknown. In a study of 544 patients with a preexisting lung cavity caused by tuberculosis, 11% had radiographic evidence

FIGURE 12-14 ■ *Aspergillus fumigatus* infection, demonstrating the branching, septate hyphae of the organism.

FIGURE 12-15 ■ The spectrum of *Aspergillus* infection. ABPA, Allergic bronchopulmonary aspergillosis.

FIGURE 12-16 ■ Computed tomography scan demonstrating an aspergilloma involving the right lower lobe.

of aspergilloma.¹²⁷ Most aspergillomas remain asymptomatic, yet some may increase in size or cause hemoptysis, requiring intervention. On the other hand, some tend to resolve spontaneously. Invasion and dissemination from an aspergilloma rarely occur. In addition to hemoptysis, which is the most common presenting symptom, chronic cough and weight loss can occur. Rupture of the cavity into the pleural space with subsequent empyema and fistula has been reported.

Radiographic imaging reveals a thick-walled cavity, typically in the upper lobe, with a mass or fungal ball within the cavity. Movement of the mass inside the cavity with position change is variable and not a reliable diagnostic test but remains an additional interesting finding (Fig. 12-17). Differential diagnoses include cavitating hematoma, neoplasm, abscess, Wegner granulomatosis, and hydatid cyst; it is important to note that aspergilloma may coexist with any of these diagnoses. Culture of the sputum may yield *Aspergillus* but is frequently negative. Serologic testing will be helpful in the setting of a suggestive radiologic finding.

Systemic antimicrobial agents, including amphotericin B, have limited use in treating aspergilloma because of poor penetration into the cavity.¹²² Asymptomatic mycetomas should be left alone. Surgical resection is indicated

if hemoptysis or other symptoms attributable to the lesion occurs and adequate pulmonary reserve is present.

Invasive Aspergillosis

Acute invasive *Aspergillus* infection is a rare but dramatic occurrence in immunosuppressed and myelosuppressed patients. Myelosuppression appears to be the greatest risk factor for invasive pulmonary aspergillosis: patients with leukemia have an incidence 20 times higher than patients with lymphoma or patients with solid organ transplants.¹²⁸ Risk factors for invasive aspergillosis include prolonged neutropenia, corticosteroid therapy, transplantation (highest risk with lung and bone marrow), hematologic malignancy, cytotoxic therapy, and acquired immune deficiency syndrome (AIDS).¹²⁹

The lower respiratory tract is the focus of the invasive infection. As a result, respiratory symptoms predominate, including fever, cough, sputum production, and dyspnea. The presence of pleuritic chest pain (caused by pulmonary infarction following vascular invasion) and hemoptysis, in the appropriate clinical setting, should alert clinicians to the possibility of the diagnosis.¹³⁰ With vascular invasion, the organism can spread to other organs, particularly the brain but also the heart and intra-abdominal organs.

Radiologic findings can be nonspecific. Rounded densities and peripheral, pleural-based infiltrates are suggestive of infarction. Typical computed tomography findings include multiple nodules, a halo sign (hemorrhage surrounding a nodule), and the air crescent sign (lucency in the region of the original nodule secondary to necrosis). The presence of *Aspergillus* spp. in sputum samples could be the result of colonization, although studies have shown that positive cultures in patients with leukemia and in those who have undergone bone marrow transplant have a positive predictive value of 80% to 90%.¹³¹ Bronchoalveolar lavage (BAL) is helpful in the diagnosis of invasive aspergillosis, particularly in patients with diffuse lung involvement. Transbronchial biopsies add little to the BAL testing except increased risk. Serologic studies are not helpful in this setting. The use of lung biopsy remains the gold standard for diagnosis but should be reserved for equivocal cases.

The mortality for invasive aspergillosis remains high,¹³² and empiric therapy should be initiated as early as possible. The treatment of choice remains amphotericin B or intravenous voriconazole, followed by oral voriconazole or itraconazole.¹²²

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) is a hypersensitivity reaction to *Aspergillus* antigens, particularly *A. fumigatus*. It is typically seen in patients with long-standing asthma or cystic fibrosis. It is believed that IgE- and IgG-mediated reactions play a central role in ABPA. The diagnosis is usually made on clinical grounds buttressed by radiologic and serologic testing. Patients present with wheezing, fever, and mucus plugging; radiologic studies show pulmonary infiltrates that tend to be in the upper lobe and central in location. Volume loss

FIGURE 12-17 ■ Posteroanterior (A) and decubitus (B) chest radiographs demonstrating an aspergilloma within a right upper lobe cavity. The fungus ball “moves” with change in patient position.

FIGURE 12-18 ■ Computed tomography demonstrating allergic bronchopulmonary aspergillosis involving the right upper lobe.

secondary to mucus impaction may be seen, appearing as bandlike opacities emanating from the hilum with rounded distal margins (Fig. 12-18). Treatment consists of oral corticosteroids to suppress the immunologic response to the *Aspergillus* antigens and the secondary inflammatory reaction. Concurrent itraconazole may be added to the regimen.

Cryptococcosis

Cryptococcus neoformans is an encapsulated yeast that is found worldwide as a soil organism. It is associated with bird (pigeon) droppings, although the birds do not serve as a vector or carrier for the microbe. The portal of entry in humans is the respiratory tract. As a result, pulmonary infection may be the first manifestation of disease but is usually variable and nonspecific. Spontaneous remission usually occurs in most patients. In those with suppressed or impaired immune systems, disseminated disease can result. *C. neoformans* has a special predilection for the meninges, and lethal meningitis can occur.

Treatment of cryptococcosis involves amphotericin B and flucytosine.¹²² Cryptococcal infections usually come to the attention of thoracic surgeons following resection of a pulmonary mass that is found to be a chronic granulomatous reaction to a prior *C. neoformans* infection. Central necrosis and cavitation are not commonly seen, as in other major pulmonary mycotic infections. These lesions often involve the lower lobe and are solid. Up to 10% of patients with a resected pulmonary lesion develop cryptococcal meningitis after resection.¹³³ If incidental resection occurs, sampling of the spinal fluid should be performed. Evidence of extrapulmonary disease or residual pulmonary disease should prompt initiation of therapy.

Mucormycosis

Mucormycosis is a rare fungal infection, commonly fatal, caused by fungi of the subclass Zygomycetes. *Mucor* species are ubiquitous and are found in soil and decaying organic debris. Infection occurs by inhalation of spores

FIGURE 12-19 ■ Posteroanterior (A) and lateral (B) chest radiographs demonstrating mucormycosis involving the left upper lobe.

and is commonly found in immunocompromised hosts. Risk factors for *Mucor* infection include neutropenia, acidosis, hyperglycemia, corticosteroid therapy, and deferrioxamine therapy. This fungus grows best in acidic, hyperglycemic environments, thus accounting for the susceptibility of patients with diabetic ketoacidosis.

Mucor infections may involve several areas of the body, including rhinocerebral, pulmonary, cutaneous, and gastrointestinal areas and the central nervous system. The rhinocerebral involvement is commonly seen in poorly controlled diabetics, and these patients may also have a pulmonary component. The pulmonary aspect typically presents with bronchopneumonia (Fig. 12-19), and progresses to invade pulmonary vessels, causing infarction.

The infection can directly invade the extrapulmonary tissues, including the chest wall and mediastinal structures.

The radiologic findings are variable and contribute little to refining the diagnosis. Culture results are usually negative; positive results strongly suggest invasive disease. Direct pathologic examination of infected tissue should reveal broad, usually nonseptate hyphae invading the tissue. The side branches are short and at a 90-degree angle.

The overall mortality rate for pulmonary mucormycosis exceeds 50%. Therapy consists of three components: correction of underlying abnormalities, such as the hyperglycemic acidotic state seen with diabetic ketoacidosis, and reversal of immunosuppression if possible; early institution of high-dose amphotericin B therapy; and aggressive surgical resection of involved lung and soft tissue, when possible.

SUMMARY

The prospect of improving the debilitating symptoms of advanced pulmonary emphysema has long attracted the interest of thoracic surgeons. Previous surgical approaches such as costochondrectomy, phrenic crush, pneumoperitoneum, pleural abrasion, lung denervation, and thoracoplasty have largely fallen out of favor.¹ Today, only three surgical procedures are offered for patients with severe emphysema refractory to intensive medical management: bullectomy, lung transplantation, and lung volume reduction surgery (LVRS). Bullectomy has roots dating to the early 1900s, when external drainage of the giant bulla was attempted to eliminate the space-occupying lesion by collapse rather than by resection. The general approach has evolved to include resection of the bulla with sparing of functional lung tissue. Lung transplantation was first successfully performed in 1963 by Hardy and colleagues,² and after a long period of incremental progress, the operation became clinically feasible in the early 1980s, first as heart-lung transplantation³ and then as isolated lung transplantation.⁴ Today, emphysema is one of the most common diagnoses leading to lung transplantation. LVRS was first proposed by Brantigan and colleagues⁵ in conjunction with lung denervation, but it was discarded after the initial experience because of a 16% mortality rate. Observations about the physiologic behavior of emphysema patients during and after lung transplantation led to the reconsideration and modification of volume reduction by Cooper and associates.⁶

PATHOPHYSIOLOGY

The destruction of pulmonary parenchyma decreases the amount of functioning lung tissue where gas exchange can take place. As lung tissue is destroyed, the organ loses

elastic recoil and expands in volume. This leads to the typical hyperexpanded chest seen in advanced emphysema patients with flattened diaphragms, widened intercostal spaces, and horizontal ribs. These anatomic changes result in the loss of normal biomechanics and bring about increased work of breathing and dyspnea.⁷ When destruction and expansion occur in a nonuniform manner, the most affected lung tissue can expand to crowd the relatively spared lung tissue to impair ventilation of the functioning lung. Obstruction in the small airways is caused by a combination of reversible bronchospasm and irreversible loss of elastic recoil by adjacent lung parenchyma. The suitability of a patient for any surgical treatment of emphysema depends in part on the relative contributions of lung destruction, lung compression, and small airways obstruction to the overall physiologic impairment.

SELECTION OF PATIENTS FOR SURGICAL TREATMENT OF EMPHYSEMA

Bullectomy, lung transplantation, and LVRS may be offered to patients who remain symptomatic despite optimal medical therapy. Initial medical treatment will include bronchodilators to treat any reversible component of airway obstruction and supplemental oxygen therapy. Smoking cessation is an absolute necessity and should be in effect for at least 6 months before surgical therapy is considered. Participation in pulmonary rehabilitation has been shown to relieve subjective dyspnea, to increase functional capabilities, and to improve subjective quality of life.^{8,9} All patients considered by the authors

for surgical treatment of emphysema are enrolled in a supervised pulmonary rehabilitation program, and their subsequent consideration for surgery is based, in part, on their compliance and progress with rehabilitation.

BULLECTOMY

Traditionally, giant bullous emphysema is characterized by a bulla or bullae that occupy approximately one third or more of the hemithorax. Most patients considered for surgery are symptomatic with dyspnea or spontaneous pneumothorax. Other rare symptoms include bleeding or infection within the confines of the bulla. Bullae treated expectantly with observation will typically demonstrate enlargement causing worsening dyspnea, although the rate of expansion is not well described. Factors making surgery less appealing include multiple smaller bullae, advanced emphysema in the nonbullous adjacent lung, and significant comorbidities. Bullectomy is performed relatively infrequently, as demonstrated by a systematic review several years ago that cited 22 individual publications on bullectomy during a 39-year period with a combined total of 476 patients.¹⁰

The operative technique depends on the anatomic details of the bulla as well as the preferred approach of the surgeon. A well-demarcated bulla with a clear pedicle can be excised with a stapler by a muscle-sparing thoracotomy or a video-assisted thoracoscopic approach. Numerous bullae or bullae that merge indistinctly with the comparatively normal adjacent lung will require a large, stapled wedge resection placed to maximize resection of destroyed lung while minimizing resection of spared parenchyma. It is unusual for a formal lobectomy to be necessary, but when a lobe is almost completely destroyed and the fissures are complete, a lobectomy is an attractive option that might reduce the risk of a postoperative air leak and prolonged chest tube drainage. Many surgeons will combine a localized pleurectomy or a pleural tent with the bullectomy to help manage the pleural space and prevent a prolonged chest tube air leak.

The safety of bullectomy in well-selected patients is demonstrated by the 2.3% mortality reported by FitzGerald and colleagues¹¹ more than 30 years ago. Our more recent results are similar, with a single death in 43 operations (2.3%).¹² Properly selected patients will experience a perioperative increase in the first second forced expiratory volume (FEV₁), and subsequently there is a very low rate of respiratory failure or need for tracheostomy. Parenchymal air leaks are the most frequent single postoperative complication. Prolonged chest tube air leaks (more than 7 days) have been reported from 53% to 75% after bullectomy.^{12,13} Air leaks may be minimized intraoperatively with the surgeon's choice of buttressed stapled lines, pleural tent, pleurectomy, biological glues, or postoperatively with ambulatory Heimlich valves.

In a prospective study with 41 patients undergoing elective surgery for bullae, the 1-year mortality rate was 7.3%, and the overall 5-year mortality rate was 12.2%.¹⁴ When a subgroup analysis was performed, it was seen that all mortality cases were from patients whose bullae were surrounded by diffuse, generalized emphysema

(rather than normal lung parenchyma).¹⁴ A small retrospective series in Iceland demonstrated no 30-day mortality, a 5-year survival rate of 100%, and an overall survival rate of 60% at 10 years.¹³ Our clinical series demonstrated a 5-year survival rate of 91%, with two late deaths attributed to pneumonia and one to pulmonary fibrosis.¹²

In general, the freedom from long-term return of dyspnea is proportional to the quality of the remaining lung after bullectomy. Our experience demonstrated an improvement in the FEV₁ from 1.2 ± 0.6 liters preoperatively to 1.9 ± 0.9 liters at 6 months and 1 year postoperatively.¹² The persistence of a measurable airflow obstruction after bullectomy underscores the presence of residual emphysema in the remaining lung, regardless of its seemingly normal appearance compared with the destroyed bullous regions. However, in a prospective series by Palla and colleagues, patients with and without underlying diffuse emphysema experienced a persistent FEV₁ benefit over 5 years of follow-up, with both groups reaching their maximum increase in FEV₁ 2 years after surgery, followed by a gradual decline through postoperative year 5.¹⁴ For all patients in this series, a significant reduction (improvement) in the dyspnea score was seen immediately after surgery and only began to increase 5 years postoperatively. Despite the late progression in dyspnea, the improvement observed in dyspnea at 5 years remained clinically significant compared with preoperative values seen at presentation.¹⁴

LUNG TRANSPLANTATION

After the initial success with single-lung transplantation for emphysema was reported,¹⁵ and the development of techniques to allow safe, bilateral lung transplantation continued to progress,^{16,17} the application of lung transplantation for severe emphysema became increasingly common. From 1995 to 2012, chronic obstructive pulmonary disease (COPD) and emphysema were the most common indications for lung transplantation and comprised 33.5% of all lung transplants.¹⁸ During this period, three single-site studies found significantly higher 5-year survival rates for patients receiving bilateral as compared with single-lung transplantation, with no difference in 30-day mortality.^{19–21} A review of the International Society for Heart and Lung Transplantation (ISHLT) database's single and bilateral lung transplants (9883 cases) from 1987 to 2006 also confirmed a significant long-term survival advantage for patients receiving a bilateral lung transplant (6.41 years vs. 4.59 years; $P < 0.0001$), and a hazard ratio of 0.89 (0.80–0.97) after propensity-based matching to control for potential confounders between these patient groups.²² A retrospective analysis of 1656 lung transplant recipients who were 60 years or older showed no difference among 30-day, 1-year, or 5-year survival rates between those who received single versus bilateral lung transplantation.²³ As an overall result of these findings, there has been an important shift in lung transplantation practice from a 27.5% bilateral rate in 1997 to 72.8% in 2011.¹⁸ Our previously published report included 306 patients, 86 of whom received a single-lung

FIGURE 13-1 ■ Survival curves for bilateral and single-lung transplant recipients at Washington University from 1988 to 2002.

transplant and 220 of whom received a bilateral transplant.¹⁹ In contrast to earlier reports from our institution, the morbidity and mortality were comparable for the two groups, with an overall hospital mortality rate of 6.2%. There were no differences in hospital stay, intensive care unit stay, or duration of mechanical ventilation. There was, however, a difference in long-term survival; the 5-year survival rate (Fig. 13-1) of the bilateral transplant recipients was 66.7%, whereas the survival rate of the single-lung recipients was 44.9%. The ISHLT database also demonstrates a significant long-term survival advantage for patients with α_1 -antitrypsin deficiency undergoing bilateral lung transplantation when compared with single-lung transplantation.¹⁸ Of note, among those patients undergoing single-lung transplantation, no difference in 30-day, 1-year, 3-year, or 5-year survival is observed based on right- or left-sided transplantation, and when such transplantations are carried out, they should be based on patient factors such as pretransplant perfusion scans.²⁴

The selection criteria for lung transplantation are chosen to identify patients with sufficient risk of death from lung disease to make the risks of the transplant operation worth bearing. In our experience, the mean supplemental oxygen requirement is slightly in excess of 4 liter/min. The typical profile of a COPD patient listed for lung transplant shows a post-bronchodilator FEV₁ of up to 20% (and frequently as low as 10% of predicted), resting PO₂ less than 55 mm Hg, significant pulmonary hypertension, hypercarbia (>55 mm Hg), life-threatening exacerbations, and severe functional limitations. Progressive elevation in PCO₂ is frequently observed in patients, with several patients undergoing transplantation with the PCO₂ in excess of 100 mm Hg. Although survival of emphysema patients has been notably difficult to predict, these patients typically exhibit an excellent survival rate on the waiting list compared with patients who have other lung diseases. In 2004, the BODE index (an acronym of the four factors that comprise the model: *b*ody mass index, *a*irflow *o*bstruction, *d*yspnea, and *e*xercise capacity) was developed and found to be a better

FIGURE 13-2 ■ Changes observed in first second expired volumes in patients after bilateral lung transplantation (BLT), single-lung transplantation (SLT), and lung volume reduction surgery (VR). FEV₁, First second forced expiratory volume.

predictor of both all-cause mortality and respiratory-related mortality than FEV₁.²⁵ For example, the highest index quartile (BODE index 7 to 10) was associated with a mortality rate of 80% at 52 months and an overall median survival of approximately 3 years.²⁵ As a result of studies using the BODE index to stratify mortality risk among patients with emphysema, the ISHLT implemented a BODE index exceeding 5 as indication for referral to a lung transplantation center and an index of 7 to 10 as an independent guideline for lung transplantation listing.²⁶

The implementation of the lung allocation score (LAS) in 2005 by the Organ Procurement and Transplantation Network altered the proportion of patients with emphysema undergoing lung transplantation after listing. Matches for donor lungs are now made on the basis of estimated mortality risk on the waiting list and estimated post-transplant survival probability. In a multicenter retrospective cohort study examining transplant characteristics before and after implementation of the LAS, a significant decrease in rates of lung transplantation for patients with emphysema was seen (from 45.9% of all transplant cases to 33.9%), with an increase in transplantation rates for patients with idiopathic pulmonary fibrosis (from 14.7% of cases to 24.6%).²⁷ No differences in hospital mortality or 1-year survival rates were detected.²⁷ Another analysis, of approximately 8000 patients listed for lung transplantation between 2002 to 2008, demonstrated that COPD patients had the lowest 6- and 12-month mortality rates on the waiting list pre-LAS and had a further significant decline in mortality rates after LAS implementation.²⁸

Initial and long-term function of patients with single or bilateral lung transplantation to treat emphysema shows a dramatic improvement in pulmonary function and exercise tolerance with elimination of the need for supplementary oxygen. Figure 13-2 demonstrates the

FIGURE 13-3 ■ Changes observed in 6-minute walk test results after single-lung transplantation (SLT), bilateral lung transplantation (BLT), and lung volume reduction surgery (VR).

magnitude of change in the FEV₁ as a result of single-lung transplantation, bilateral lung transplantation, and LVRS as reported by Gaissert and colleagues.²⁹ Figure 13-3 shows a similar stratified analysis for exercise tolerance as measured by 6-minute walking distances. Although the improvement in both outcome measures is greatest for patients who underwent bilateral lung transplantation and least for those who underwent LVRS, the absolute differences in exercise tolerance are much less than those seen in pulmonary function. Improvements in quality-of-life measures have also been documented among lung transplant patients with a BODE index greater than 5 (with mean time of assessment 4 months after lung transplantation).³⁰

The disadvantages of lung transplantation are well known. First, the lack of available donor lungs can lead to wait times in excess of a year. Once lungs become available, the initial morbidity and mortality rates of lung transplantation are higher than those reported for lung volume reduction, with 30-day mortality variously described as 5% to 15% but typically closer to the lower end of that range. The presence of allograft lungs necessitates lifelong immunosuppression, incurring higher medical costs to the individual and society. It also predisposes the patient to increased risk of neoplasm (as well as increased growth rate of occult cancers with poor comparative survival versus non-immunosuppressed patients for any given stage) and infection compared with non-immunosuppressed patients. Finally, the risk for development of chronic lung allograft dysfunction (CLAD) increases as a function of time following transplantation, reaching 50% to 60% by 5 years. A retrospective study of 425 bilateral lung transplants from the ISHLT/United Network for Organ Sharing (UNOS) registry identified a survival difference when analyzed by age, with 30-day, 1-year, and 5-year survival rates for patients younger than

50 years old equal to 94.9%, 84.7%, and 68.2%, respectively, and patients 50 to 60 years old with rates of 93.0, 79.7, and 60.5%.³¹

A controversial aspect of lung transplantation had been the question of whether it conveys a survival benefit to the patient with emphysema, with literature from the past decade divided.²⁴⁻²⁹ Of note, when patients transplanted for emphysema are stratified either by FEV₁ or BODE index, survival benefit with lung transplantation is seen for the most severe categories of each measurement. For example, in a numerical simulation based on a UNOS database of 8182 COPD patients on the waiting list for lung transplantation since 2004, it was calculated that 79% of patients with an FEV₁ less than 16% of the predicted value would gain an average of an additional year of life expectancy (in comparison to only 44.6% of listed patients gaining an additional year when not stratified by FEV₁).³² A survival benefit was also seen in a single-center retrospective analysis when COPD patients receiving lung transplantation were stratified by BODE index of 7 or higher.³³ It is likely that the Lung Allocation System will optimize the life extension caused by lung transplantation by balancing the goals of transplanting the candidates with the lowest life expectancy on the wait list while selecting those most likely to survive and thrive postoperatively (Fig. 13-4).

Techniques

Our current approach to a bilateral sequential transplantation involves bilateral anterior thoracotomies in the fourth (or fifth) interspace. The internal mammary artery is ligated and divided bilaterally. The fourth rib is shingled anteriorly by resecting 1 cm of the costal cartilage at the sternal border. More mobility is obtained by dividing the intercostal muscle from within the pleural space back as far as the posterior axillary line. Should additional access to the thorax become necessary during the operation, the sternum can be divided transversely at the fourth interspace, and the entire chest is clamshelled open. The least functional lung, as determined by preoperative quantitative ventilation and perfusion scans, is resected and replaced first. Preliminary dissection of both lungs shortens the time that the first implanted lung is exposed to the entire cardiac output and thus lessens the likelihood of reperfusion edema.

The pulmonary arteries and veins are dissected beyond their primary bifurcations to preserve the length of the main trunks. The right pulmonary artery is usually transected by a vascular stapling device 1 cm beyond the ligated first branch to the right upper lobe. The left pulmonary artery is kept longer and transected between staple lines beyond the second branch to the left upper lobe. The vein branches are usually not stapled; rather, they are double ligated and divided at their secondary branch points to save length for the future recipient atrial cuff. The arterial and venous dissection and division are accomplished before the bronchial division to avoid prolonged contamination of the operative field by the open distal airway. The bronchus is transected between cartilaginous rings, and the posterior bundle of lymphatics and bronchial arteries is exposed to facilitate ligation and

FIGURE 13-4 ■ Relative risk of death after lung transplantation compared with risk faced by remaining on the waiting list, stratified by underlying diagnosis leading to transplantation.

subsequent division. The pulmonary artery stump is mobilized centrally, then grasped with a clamp and retracted anteriorly to afford better access to the posterior bronchus. The pulmonary vein stumps are then grasped and retracted anteriorly and laterally to permit circumferential opening of the pericardium. With the pericardium freed, the vein stumps are then retracted and temporarily fixed anteriorly. This provides an excellent view of the bronchus, which is then mobilized well into the mediastinum and divided. Meticulous hemostasis in the mediastinum is achieved at this point, with the knowledge that reaching this portion of the operative field after implantation of the graft lung will be extremely difficult.

Meanwhile, the donor lung is prepared on the back table. The donor bronchus is divided immediately proximal to the upper lobe orifice. Care is taken to minimize dissection of the donor bronchus to preserve collateral flow through the peribronchial nodal tissue. The pulmonary artery and left atrial cuffs are freed from any pericardial attachments that may cause kinking after the anastomosis is completed.

Once the native lung is removed, the donor lung is placed into the chest and kept cold with iced saline and slush. We conduct the anastomoses from posterior to anterior in the following sequence: bronchus, artery, and atrium. The first stitches are 4-0 polydioxanone (PDS) sutures placed at the two corners of the bronchial anastomosis at the medial and lateral junction of the membranous and cartilaginous airways. These sutures are tied, and one end is used to join the donor and recipient membranous airways in a continuous suture. The cartilaginous rings of the donor and recipient are joined with interrupted figure-of-eight 4-0 PDS sutures.

The second anastomosis is the pulmonary artery. The pulmonary artery (which has already been extensively and circumferentially dissected into the mediastinum) is clamped centrally, with care taken to avoid including the Swan-Ganz catheter in the jaws of the Satinsky clamp. The vascular staple line is resected at a location that matches the size of the donor and recipient artery. A larger recipient artery can be divided beyond the first ligated branch to match a smaller donor artery; a smaller recipient artery is usually divided proximal to the first branch, or through it, to maximize circumference. The donor pulmonary artery is trimmed to an appropriate length, and the anastomosis is created with running 5-0 Prolene suture. This anastomosis must be made with precise, small suture bites to avoid any anastomotic stricture.

The atrial anastomosis is performed last. A Satinsky clamp is placed centrally on the atrium. Placement of this clamp too centrally can reduce venous drainage from the contralateral lung and decrease cardiac output, whereas placement of the clamp too peripherally will compromise the recipient atrial cuff. The ties are then cut off the recipient vein stumps, and the bridge of atrium between vein stumps is divided to create the atrial cuff. The anastomosis is performed with 4-0 Prolene suture, and the last few sutures are left intentionally loose to allow flushing and de-airing of the graft and the recipient atrium. For this maneuver, the lung is partially inflated, and the pulmonary artery clamp is loosened momentarily. The lung is flushed to force out the residual pulmonary perfusate solution. The pulmonary artery clamp is then reapplied, and the atrial clamp is opened momentarily to completely de-air the atrium. The atrial sutures are then secured and the clamps removed. All suture lines are then checked for hemostasis as ventilation and perfusion are restored.

VOLUME REDUCTION

The concept of LVRS is an extension of the bullectomy operation, in which destroyed tissue is resected to facilitate better function of the remaining lung that is

relatively spared from major emphysematous changes. The advantages of lung volume reduction for carefully selected candidates include relief of dyspnea and improvement of functional capabilities without the cost and adverse side effects of organ transplantation. There is no built-in waiting time as with transplantation; as soon as candidates can reach the pulmonary rehabilitation exercise goals, they are ready for the procedure (Box 13-1).

Many groups in previous decades have reported independent results for LVRS, and these results have consistently shown benefit to the recipient with acceptable mortality and varying morbidity.³⁴⁻³⁸ Successful lung volume reduction programs report meticulous selection of patients (Table 13-1), methodical preparation of patients with reduction of risk factors, and attentive post-operative care. In contrast to patients considered for lung transplantation for severe emphysema, patients being considered for LVRS may be slightly older (up to 75 years of age), may have a slightly higher preoperative post-bronchodilator FEV₁ (<40% predicted), and must demonstrate heterogenous emphysematous changes on

high-resolution computed tomography (HRCT). Significant hypercarbia (PCO₂ > 55 mm Hg) or pulmonary hypertension (PA systolic > 45 mm Hg) are contraindications to LVRS. Gains of 20% to 35% in FEV₁ have been reported for unilateral operations, and improvements of 40% to 80% are seen with bilateral operations. Most authors also reported substantial gains in exercise tolerance, freedom from oxygen use, freedom from steroid use, and subjective quality of life.

Ciccone and associates³⁹ reported long-term results in 250 bilateral LVRS recipients. After a median follow-up of 4.4 years, the 5-year survival was estimated to be 68%. Of these 250 patients, 18 had gone on to lung transplantation after a median interval of 4.3 years. Five years after surgery, the mean change in FEV₁ had declined to a 7% increase, yet 53% of the patients demonstrated persistence in benefit over preoperative FEV₁ values. This finding takes on greater importance when considering the relentless deterioration in FEV₁ seen despite maximal medical management.

To date, the National Emphysema Treatment Trial (NETT) has been the largest and most comprehensive

BOX 13-1 Indications and Contraindications for Lung Volume Reduction Surgery and Lung Transplantation

INDICATIONS COMMON TO BOTH PROCEDURES

Emphysema with destruction and hyperinflation
Marked impairment (FEV₁ < 35% predicted)
Marked restriction in activities of daily living
Failure of maximal medical treatment to correct symptoms

CONTRAINDICATIONS TO BOTH PROCEDURES

Abnormal body weight (<70% or >130% of ideal)
Coexisting major medical problems increasing surgical risk
Inability or unwillingness to participate in pulmonary rehabilitation
Unwillingness to accept the risk of morbidity and mortality of surgery
Tobacco use within the past 6 months
Recent or current diagnosis of malignant disease
Increasing age (>65 years for transplantation, >70 years for volume reduction)
Psychological instability, such as depression or anxiety disorder

DISCRIMINATING CONDITIONS FAVORING LUNG VOLUME REDUCTION SURGERY

Marked thoracic distention
Heterogeneous disease with obvious apical target areas
FEV₁ > 20% predicted
Age between 60 and 70 years

DISCRIMINATING CONDITIONS FAVORING LUNG TRANSPLANTATION

Diffuse disease without target areas
FEV₁ < 20% predicted
Hypercapnia with PaCO₂ > 55 mm Hg
Pulmonary hypertension
Age younger than 60 years
α₁-Antitrypsin deficiency

TABLE 13-1 Selection Criteria for Lung Volume Reduction Surgery

Inclusion Criteria	Exclusion Criteria
General	
Disability despite maximal rehabilitation	Inability to participate in rehabilitation
Cessation of tobacco use > 6 months	Continued use of tobacco
Patient's expectation of goals reasonable	Significant comorbidity
	Previous pleurodesis or thoracotomy
	Underweight, overweight
Anatomic-Radiographic Evaluation	
Marked emphysema	Bronchiectasis
	Minimal radiographic emphysema
Heterogeneously distributed emphysema	Homogeneously distributed emphysema
Target zones of poorly perfused lung	No target zones
Areas with better preserved lung	No preserved lung tissue
Marked thoracic hyperinflation	Chest wall or thoracic cage abnormalities
Physiologic Evaluation	
Marked airflow obstruction	Minimal to moderate airflow obstruction
Marked hyperinflation	Minimal to moderate thoracic hyperinflation
Alveolar gas exchange	Markedly disordered alveolar gas exchange
DL _{CO} < 50% (steady state)	DL _{CO} < 10%
	PaCO ₂ > 60 mm Hg
Cardiovascular function	Cardiovascular function
Essentially normal ejection fraction	Mean pulmonary artery pressure > 35 mm Hg
	Left ventricular ejection fraction < 40%
	Significant coronary artery disease

randomized control trial to evaluate the role of LVRS in severe emphysema. After completing a pulmonary rehabilitation program, 1218 patients were randomized to either bilateral LVR surgery or continued best medical therapy between January 1998 and July 2002.⁴⁰ This multicenter trial reported a 90-day surgical mortality of 7.9%, which did not differ according to surgical approach (sternotomy vs. video-assisted thoracoscopic surgery) or by center. Although there was a significant difference between the 90-day surgical mortality and the 90-day mortality of those participants that remained in the medical arm (7.9% vs. 1.3%, respectively; $P < 0.001$), at the 2-year follow-up there was no difference in total mortality.⁴⁰ When high-risk patients were excluded (defined as participants with an FEV₁ of up to 20% predicted and either diffusing capacity for carbon monoxide [DL_{CO}] up to 20% or homogenous emphysema), the 90-day surgical mortality decreased to 5.2%.⁴⁰ Cooper and colleagues refrained from offering LVRS to patients with homogeneous emphysema from the outset of our experience, but the results obtained in this high-risk group were different from those reported by the NETT. Meyers and colleagues reported that patients with both FEV₁ and DL_{CO} of less than 20% predicted values experienced a perioperative mortality of 5% and durability of benefit that was no different from that experienced by the rest of the LVRS cohort.⁴¹ The survival curves from that study are shown in Figure 13-5.

Improvements in exercise capacity, 6-minute walk distance, percent predicted FEV₁, quality-of-life measures, and dyspnea scores were significantly higher in the NETT surgery group at all time points (6, 12, and 24 months).⁴⁰ However, when patients were divided into four subgroups based on location of disease (upper lobe vs. other) and exercise capacity (high vs. low), important outcome differences were detected (Fig. 13-6). For patients with upper lobe disease, those with low exercise capacity had significantly improved survival (risk ratio [RR] for death = 0.47; $P = 0.005$), workload capacity, and quality-of-life measures, whereas those with high exercise capacity preop showed benefits in workload

capacity and quality-of-life measures only.⁴⁰ For patients with non-upper lobe disease, those with low exercise capacity showed significant improvements in quality-of-life measures only, whereas those with high exercise capacity had no improvements in any category and in fact were at increased risk of death (RR = 2.06; $P = 0.02$).⁴⁰ These results still inform surgeons and payers regarding suitable candidate selection for LVRS.

Subgroup analysis of patients with α_1 -antitrypsin deficiency enrolled in NETT demonstrated higher 2-year mortality with surgery compared with medical management (20% vs. 0%) and decreased duration of benefits in FEV₁.⁴² Previous single-center studies had also demonstrated that improvement in dyspnea scores and lung function testing in α_1 -antitrypsin-deficient patients is of lower magnitude and shorter duration when compared with those who had more typical emphysema.^{43,44}

At 5 years of follow-up in NETT, the total mortality rate for all participants in the surgical group was

FIGURE 13-5 ■ Kaplan-Meier survival graph after bilateral lung volume reduction surgery (LVRS).

FIGURE 13-6 ■ National Emphysema Treatment Trial survival curves.

significantly lower than that in the “best medical care” cohort (overall RR = 0.85; $P = 0.02$). Quality-of-life measures were persistently higher, and exercise capacity remained significantly improved in the surgical patients for 3 years.⁴⁵ Subgroup analysis at 5 years demonstrated a continued survival advantage for the upper lobe, low exercise capacity participants only (RR = 0.57; $P = 0.01$). For the non-upper lobe disease group with low exercise capacity, the benefit in quality-of-life measures only persisted for 2 years, less than in both of the upper lobe disease groups.⁴⁵ A later exploratory analysis retrospectively analyzed survival data based on perfusion scintigraphy and found that the survival advantage for the upper lobe–predominant disease and low exercise capacity group was only significant when low upper zone perfusion was also documented (defined as less than 20% of total lung perfusion to the upper third of both lungs).⁴⁶ In this analysis, a significant survival advantage was also detected among the upper lobe disease patients with high exercise tolerance and low upper zone perfusion (RR 0.70; $P = 0.02$).⁴⁶ Figure 13-7 shows a perfusion scintigram that demonstrates the absence of apical perfusion—a pattern often seen in ideal candidates for LVRS.

The typical postoperative hospitalization after LVRS is described as 8 to 10 days, with variation in length of stay often attributed to persistent air leaks and atrial fibrillation. In the NETT trial, 90% of patients were

reported as having a postoperative air leak after LVRS, with a median duration of leak of 7 days.⁴⁷ Significant increases in risk for incidence and duration of air leak were found among patients with upper lobe disease, significant pleural adhesions, patients using inhaled steroids, and those with lower predicted FEV₁.⁴⁷ No association was found between rate or duration of air leak and surgical approach, buttressing of staple line, stapler brand, or intraoperative adjunctive procedures (pleural tenting, fibrin glue, or chemical pleurodesis).⁴⁷ Of note, 96.4% of patients in the NETT trial received buttressed staple lines, so the power to detect a difference is small. Other studies have detected a significant reduction in air leak duration and length of stay with buttressing.^{48,49} For patients experiencing air leak in NETT, postoperative stay was significantly longer (11.8 vs. 7.6 days; $P = 0.0005$).⁴⁷ Long-term complications past 30 days are rare, but there have been case reports describing expectoration of staples and bovine pericardial strips ranging from 6 to 20 months after surgery.^{50,51} The most serious sequelae of this have been identification of an associated pneumonitis or pneumonia and treatment with antibiotics.^{50,51} No cases demonstrated a subsequent bronchopleural fistula, likely because of the length of time since the original surgery.

Reoperation for further resection after initial LVRS is extremely rare. One group reported a series of 17 patients that demonstrated recurrent evidence of regional lung hyperinflation and loss of clinical benefit after initial LVRS.⁵² The various methods used for repeat intervention included completion lobectomy in approximately 40%, nonanatomic resection in 30%, and awake lung plication under epidural anesthesia in the remaining 30%.⁵² Although this led to improvements in FEV₁, forced vital capacity (FVC), residual volume (RV), 6-minute walk test, and dyspnea scores at 1-year follow-up, the perioperative mortality rate was 11.7%, higher than typically seen for initial LVRS.⁵²

Techniques

We currently favor a video-assisted thoracoscopic surgery (VATS) approach for bilateral lung volume reduction procedures because of the exposure and flexibility that it provides with a minimum of morbidity. In the NETT experience, there was no difference in mortality between median sternotomy and VATS. However, the cost of operation, median hospital length of stay, and percentage of patients experiencing independent living at 1 month postoperatively showed significant benefits for VATS in comparison with median sternotomy.⁵³

Many patients with severe emphysema have a significant element of chronic bronchitis with increased sputum production. After induction of anesthesia, a single-lumen endotracheal tube is placed and flexible bronchoscopy is performed to suction secretions and to obtain a specimen for Gram stain and culture. If thick, tenacious secretions are encountered, a mini-tracheostomy may be inserted at the end of the operative procedure to facilitate postoperative pulmonary toilet. After bronchoscopy, the single-lumen endotracheal tube is replaced with a left-sided double-lumen tube.

FIGURE 13-7 ■ Pulmonary perfusion scintigraphy demonstrating typical upper lobe–predominant emphysema that is viewed as the most suitable morphology for lung volume reduction surgery. *LPO*, Left posterior oblique; *Lt Lat P*, left lateral posterior; *RPO*, right posterior oblique; *Rt Lat A*, right lateral anterior.

Ventilation to the right lung is then suspended while ventilation to the left lung is continued. Care is taken by the anesthesiologist to avoid overinflation of the left lung, and airway pressures are generally restricted to the range of 15 to 20 cm H₂O pressure. Hypercapnia may well occur, but this is usually well tolerated. The patient may be placed in the supine position or in the respective lateral decubitus position depending on surgeon preference. The first trocar is placed in the seventh intercostal space and will serve as the thoracoscopic port. The working ports can be placed at the fourth or fifth intercostal space lateral to the midclavicular line. Several minutes after ventilation is suspended to the right lung, the right middle and lower lobes are usually well deflated and become progressively atelectatic, while continued inflation from upper lobe disease may still be visualized. Compression with a sponge on a ring clamp through the working port will help gradually deflate the upper lobe. The pulmonary ligament is rarely divided. Dense adhesions may be present if there have been prior episodes of pneumonia.

For upper lobe disease, 70% to 80% of the right upper lobe is excised with multiple applications of a linear stapler buttressed with strips of bovine pericardium or other similar material. Recall that the NETT trial showed no benefit for buttressing, but most cases involved the use of such material. A long curved clamp can be placed through the instrument port and applied to the lung to create a linear “crush” mark before application of the stapler. The staple line (with buttressing strips) is started at the anterior segment of the right upper lobe next to the mediastinum and is continued posteriorly. Of note, adjustments to this staple line trajectory may be made depending on lung perfusion studies. Care should be taken to avoid crossing the fissure because this can damage the superior segment of the lower lobe or tether the apex of the superior segment to the remaining upper lobe and prevent the superior segment from filling the apex of the chest.

We prefer to use a single line of excision to remove most of the right upper lobe rather than using multiple excisions, remembering that the goal is to reduce volume adequately, not to remove all of the severely diseased lung tissue. Occasionally, the apex of the upper lobe will be densely adherent to the apex of the chest and to the superior mediastinum. In such cases, it may be easier first to transect the upper portion of the lobe before attempting to dissect the apical and mediastinal adhesions. Once the transection has been accomplished, the specimen can be more easily detached from the chest wall and mediastinum by blunt dissection, cautery, or even a linear stapler, leaving a small remnant of the lung attached to the mediastinum, if necessary, to avoid injury to the phrenic nerve.

After upper lobe resection, the chest is filled with warm saline and the lung is gently inflated. Ordinarily, there are no air leaks at this time. It is not uncommon to find that the reexpanded, remaining lung does not completely fill the apex of the chest. We have considered the use of a pleural tent in this situation but now reserve it for rare cases, in particular when the remaining lung is tethered in the chest by virtue of adhesions to the chest wall or diaphragm. It has not been our practice to do

pleurodesis either by abrasion or by talc, even if the patient is not a potential candidate for subsequent lung transplantation. One chest tube is placed in the pleural space and brought out through the camera port.

Ventilation is shifted from the left lung to the right lung. With upper lobe–predominant disease, the goal is to excise the superior subdivision of the left upper lobe, leaving the lingula intact, because this is usually much less diseased. Unlike the right side, the superior segment of the left lower lobe usually reaches easily to the apex of the chest after the apical resection.

The upper one half to two thirds of the left upper lobe is excised with multiple applications of the stapler. The line of excision is usually parallel to the oblique fissure separating the upper and lower lobes. As on the right side, care is taken to avoid stapling across the fissure into the superior segment of the left lower lobe. After left upper lobe excision, the lung is reinflated and inspected for air leaks. One chest tube is placed as on the right.

After completion of the operation, the double-lumen tube is removed in the operating room. If a mini-tracheostomy is thought to be necessary on the basis of the initial bronchoscopy, this is placed immediately after removal of the double-lumen tube, generally with a 4-mm-diameter mini-tracheostomy.

COMBINATIONS OF LUNG TRANSPLANTATION AND LUNG VOLUME REDUCTION

Combinations of LVRS and lung transplantation have been reported in anecdotal clusters of patients. The combined approaches include volume reduction as a bridge to transplantation, simultaneous single-lung transplantation and unilateral volume reduction to prevent native lung hyperexpansion, early post-transplantation unilateral volume reduction to treat acute native lung hyperexpansion, and late unilateral volume reduction to treat chronic native lung hyperexpansion.

When single-lung transplantations are performed in patients with emphysema, dynamic hyperinflation is a phenomenon that can arise during ventilation through a standard single-lumen endotracheal tube. Although the transplanted lung may display a restrictive physiology with low compliance (especially in the setting of reperfusion injury) and require significant positive pressure ventilation, this will cause the native high compliance lung to undergo significant inflation, possibly resulting in hemodynamic compromise. This can be minimized by placing a double-lumen endotracheal tube and providing independent ventilation, or expediting extubation as soon as appropriate. However, this phenomenon may also be seen months after transplantation and extubation with more mild to moderate symptoms. Todd and colleagues⁵⁴ reported the Toronto experience with simultaneous unilateral volume reduction after single-lung transplantation to prospectively improve overall lung function. They experienced no additional postoperative complications, and the pulmonary function at 3 months was better than expected compared with historic controls receiving a

single-lung transplant alone. Yonan and colleagues⁵⁵ retrospectively analyzed 12 patients who experienced native lung hyperexpansion after single-lung transplantation. In their analysis of risk factors, lower pretransplantation FEV₁, higher RV, and pulmonary hypertension were all associated with a higher risk for native lung hyperexpansion. They did not perform nor did they advocate volume reduction surgery simultaneously with single-lung transplantation for emphysema.

The concept of a combined procedure was introduced to the medical literature by Zenati and colleagues⁵⁶ in 1995. Meyers and colleagues described 99 of 200 patients who underwent bilateral LVRS and who were thought to have been eligible for transplantation.⁵⁷ With a median follow-up of 5.1 years, 32 of the 99 had been listed for transplantation and 15 had actually undergone transplantation.⁵⁷ The Kaplan-Meier curve depicting freedom from listing and freedom from transplantation is shown in Figure 13-8. The only preoperative or operative factor that was predictive for the subsequent need for transplantation was a lower lobe rather than an upper lobe LVRS procedure.

One potential benefit for the patient successfully completing volume reduction surgery is the possibility that transplantation might be avoided altogether by an excellent response to volume reduction. A second possibility is that transplantation is delayed by several years and the patient is transplanted with a later cohort with the possibility of improved techniques, better immunosuppression, and overall better survival. Finally, because the hazard rate of death after lung transplantation is higher than the hazard rate of death after LVRS, anything that can safely delay entry onto the steeper survival curve may be advantageous.

However, the potential benefit of LVRS as a bridge to transplantation has limitations for many patients with severe emphysema. The anatomic and physiologic criteria that are now known to allow for significant improvement with LVRS are much more restrictive than the

criteria for transplantation, so it is unlikely that a large fraction of emphysema candidates for transplantation could be safely and successfully treated with volume reduction. Also, the challenge of how to treat a patient near the upper age limit eligible for transplantation remains a dilemma. Finally, for many patients with LVRS prior to bilateral lung transplantation, this occurred not as a bridging plan but as a pragmatic response to increasing symptoms after observing loss of the initial respiratory benefit from the LVRS procedure.

The technical logistics of performing bilateral lung transplantation after LVRS can be challenging. Although previous studies reported no differences in the need for reoperation, hospital length of stay, longitudinal lung function testing, or survival in patients receiving LVRS prior to transplantation, it is important to note that most patients received unilateral lung transplantation only.^{58,59} A recent series found that when compared with other bilateral lung transplant patients, patients with a prior history of LVRS had significantly longer operating room times, more frequent use of cardiopulmonary bypass (45% vs. 16%; $P < 0.05$), longer time on cardiopulmonary bypass, higher transfusion rates, and more adhesions to the chest and hilum.⁶⁰ In terms of perioperative outcomes, patients with LVRS prior to bilateral lung transplantation were also found to have significantly more reexplorations because of bleeding, more frequent need for phrenic nerve surgery, a higher rate of renal insufficiency requiring dialysis, longer intensive care unit stay (14.4 vs. 3.2 days; $P < 0.05$), lower FEV₁ (56.7 ± 29.1 vs. 78.8 ± 23.5 ; $P < 0.05$), and shorter distances on 6-minute walk tests.⁶⁰ Of note, longer ischemic time, chylothorax, primary graft disease requiring extracorporeal membrane oxygenation (ECMO), and in-hospital death numbers approached statistical significance.⁶⁰ The realities of the higher risks incurred when performing bilateral lung transplantation after LVRS should certainly influence both the patient consent process and operating room preparation.

The use of LVRS for late or chronic native lung hyperexpansion after single-lung transplantation is increasingly rare and anecdotal as the proportion of single-lung transplants continue to decrease. Kroshus and colleagues⁶¹ described three patients who were treated with unilateral LVRS for native lung hyperinflation and post-transplantation dyspnea that was not attributable to infection or rejection. LVRS was performed 12, 17, and 42 months after the initial lung transplantation, and all patients experienced a substantial relief in dyspnea with an improvement in exercise tolerance and an improvement in the appearance of the chest radiograph. A similar report by Le Pimpec-Barthes and associates⁶² described successful treatment of symptomatic native lung hyperexpansion by volume reduction of the native side in the form of a right upper lobectomy.

BRONCHOSCOPIC TREATMENT OF EMPHYSEMA

On the basis of improvements seen with LVRS, two main endoscopic approaches to reduce hyperinflation in

FIGURE 13-8 ■ Freedom from listing and freedom from transplantation in 99 patients thought to be eligible for either lung volume reduction surgery (LVRS) or transplantation at the time of bilateral LVRS operation.

patients with severe emphysema have been developed and investigated.

Endoscopic Placement of One-Way Valves

One approach involves placement of one-way valves with bronchoscopy in the segmental bronchi of markedly destroyed and hyperinflated portions of the lung. It was anticipated that such valves would allow deflation and secretion drainage from these segments while limiting distal airflow in. Over time, it was postulated that this would facilitate atelectasis and volume reduction in those segments. In a single-center nonrandomized trial of patients with heterogeneous emphysema, unilateral one-way intrabronchial valves were placed at target areas defined by HRCT and lung perfusion scans.⁶³ An average of 3.6 valves were placed for each patient, and all lobes were amenable to valve placement. Of note, when performing valve placement in a right middle lobe target area, the right middle lobe was always treated together with the right upper lobe.⁶³ Significant improvements were detected post procedure in supplemental oxygen use, FEV₁, FVC, RV, 6-minute walk test, and dyspnea scores.⁶³ The 6-minute walk test and dyspnea score improvements were the only outcomes that remained significant at the 5-year follow-up.⁶³ When participants' HRCT scans were evaluated for complete versus incomplete fissure demarcation, patients with complete fissures continued to have improvement in supplemental oxygen use and RV at 5 years. Furthermore, this group had a significantly improved survival advantage (83.3% vs. 24% at 100 months; $P = 0.003$).⁶³ An additional technique that has been developed to document the presence of collateral ventilation to a potential target area involves occluding the airway of interest with a catheter balloon and subsequently measuring collateral ventilation through airflow and pressure measurements of the isolated segment through a console system (Chartis).⁶⁴

In a multicenter trial with intrabronchial valve placement in patients with heterogeneous upper lobe-predominant emphysema, significant improvements were detected in the Saint George Respiratory Questionnaire at 1-, 3-, and 6-month follow-ups.⁶⁵ Patients that showed similar criteria to the high-risk category in NETT were excluded. No significant changes in pulmonary function or 6-minute walk test were detected.⁶⁵ Of note, approximately 25% of patients had valves removed at various time points for LVRS (with reasons including pneumonia in the area of the valves, nonresponders requesting removal, and in one episode, acute removal for a patient with wheezing and chest pain).⁶⁵ No episodes of valve erosion, migration, or hemoptysis were reported.⁶⁵ In the Endobronchial Valve for Emphysema Palliation (VENT) trial, another multicenter randomized trial, a small significant difference in the FEV₁ and 6-minute walk test between the endobronchial valve group and the standard medical care group was detected at 6 months, although much of this significance was attributed to continued loss of FEV₁ in the standard care group.⁶⁶ Patients receiving endobronchial valves were noted to have increased rates

of COPD exacerbation requiring hospitalization and pneumonia in the target lobe.⁶⁶

Airway Bypass

Many patients with crippling, end-stage emphysema are not suitable candidates for LVRS because of a homogeneous pattern of destruction. In these patients, there are no "target areas" that could be excised for LVRS or placement sites for endobronchial valves. Nonetheless, these patients are subject to the same crippling effects of hyperinflation as are other end-stage emphysema patients. With the goal of reducing hyperinflation in these patients, airway bypass can be performed to provide direct communication between segmental bronchi and adjacent lung parenchyma. Stents are placed through the bronchial wall, with one end of the stent in the airway and the other in the lung parenchyma. Because of the extensive collateral ventilation that may be present in such patients, several airway bypass stents may be needed. The Exhale Airway Stents for Emphysema (EASE) trial was a randomized, double-blinded international trial that examined the use of airway bypass versus sham control (bronchoscopy only) in patients with homogeneous emphysema and severe hyperinflation.⁶⁷ Patients in the airway bypass arm could receive up to six stents, with a maximum of two stents per lobe (excluding the right middle lobe).⁶⁷ Although postprocedure lung function testing showed significant improvement (increased FEV₁, decreased RV, and increased FVC), these benefits did not persist at 1 month or beyond.⁶⁷ In terms of symptomatic improvement, there was a significant benefit in the St. George's respiratory questionnaire (SGRQ) at 1 month, but that outcome also did not persist in later follow-up (from 3 months to 1 year) when compared with the control group.⁶⁷ On 6-month follow-up imaging, only 25% of patients had all stents present (most presumably lost as a result of expectoration), and of those with remaining stents, only 21% had retained patency.⁶⁷ Based on this trial, it is not likely that airway bypass results in any durable benefits for either treatment or palliation of severe hyperinflation.

Nitinol Airway Coils

At the time of this chapter writing, there is enthusiasm in some centers for another novel approach to improve symptoms of advanced emphysema. Initial pilot studies are under way of the use of nitinol stents to shrink emphysematous upper lobes and enhance ventilation and perfusion of the other, spared, areas of the lung. The procedure has been dubbed LVRC (lung volume reduction endobronchial coils) and the generic procedure to address symptoms endobronchially has been named BLVR (bronchoscopic lung volume reduction). Preliminary small trials have shown encouraging findings with improved pulmonary function, better exercise tolerance, and improved subjective symptom controls. Currently, these devices are for investigational use only and the reader will have to check recent reports for updates on the fate of LVRC and any additional entries to the category of BLVR interventions. A large, multicenter trial

with a planned enrollment of 315 patients (the RENEW trial) will help decide the fate of this latest entry into the arena of nonsurgical LVRS analogues.

SUMMARY

Although bullectomy, LVRS, and lung transplantation are similar in that each represents a surgical procedure aimed at improving the physiology and symptoms of severe pulmonary emphysema, they are unique in their ideal selection criteria and expected outcomes. We favor a meticulous selection process in which all options are considered and ultimately tailored to the patient's anatomic and physiologic features. Patients referred with a functionless, space-occupying bulla that compresses relatively normal adjacent lung will be offered thorascopic or open bullectomy. Patients with ideal circumstances for LVRS—that is, hyperinflation, heterogeneous distribution of disease, FEV₁ greater than 20%, and normal PCO₂—may be offered LVRS. Finally, patients with diffuse disease, lower FEV₁, hypercapnia, and associated pulmonary hypertension are directed toward transplantation. LVRS has not been a satisfactory option for patients with α_1 -antitrypsin deficiency, and we prefer transplantation in these cases. With strict adherence to these criteria, we find that very few emphysema patients are serious candidates for any surgical procedures. Combinations of lung volume reduction and lung transplantation, either simultaneously or sequentially, are possible but rarely necessary. Because many of the intrabronchial valve trials excluded patients that were considered high risk in the NETT trial, the main population for which we have data regarding endobronchial valve palliation are patients that either decline LVRS or have hindering medical comorbidities. Airway bypass at this time remains a procedure with only a short-term benefit, with no evidence of long-term palliation. Novel strategies will need to pass through rigorous challenges that have led to the dismissal of many such interventions in the past.

RESULTS

PEDIATRIC LUNG TRANSPLANTATION

SUMMARY

The first successful human lung transplant was done in 1983 by the Toronto Lung Transplant Group.¹ Thirty years have passed since this landmark operation and more than 15,000 lung transplants have been done. Lung transplantation is now the preferred treatment option for a variety of end-stage pulmonary diseases. Remarkable progress has been made through refinements in technique and a better understanding of transplant immunology and microbiology. Despite these improvements, a shortage of donors and chronic graft dysfunction continue to prevent lung transplantation from reaching its full potential. Attempts made to address the donor shortage include using marginal donors, living-lobar donors, non-heart-beating donors, and split-lung donor techniques. Chronic graft dysfunction is the major factor that limits long-term survival. Extensive research efforts are underway to find methods to overcome this and prolong survival in patients undergoing lung transplantation.

HISTORICAL ASPECTS

In 1947, Vladimir Demikhov performed the first lung transplant in a dog.^{2,3} The dog survived 7 days, subsequently dying from complications of bronchial dehiscence. Dr. James D. Hardy and colleagues performed the first human lung transplant in 1963.⁴ Although their patient died after 18 days, their brief success demonstrated the technical feasibility of the operation and stimulated worldwide interest in lung transplantation. Over the next 20 years, approximately 40 lung transplants were attempted, but none achieved long-term success.⁵ The only recipient discharged from the hospital was a 23-year-old patient of Derom and colleagues,⁶ who left the hospital 8 months after transplantation and died a short time later as a result of chronic rejection, sepsis, and bronchial stenosis. Most patients in this era died within 2 weeks of lung transplantation as a result of primary graft failure, sepsis, or rejection. The most frequent cause of death

beyond the second week was bronchial anastomotic disruption.

The Toronto Lung Transplant Group's first attempt at lung transplantation, in 1978, ended with the patient dying after a bronchial dehiscence.⁷ Through experimental studies, this group discovered that high-dose perioperative steroids hindered bronchial anastomotic healing,⁸ and that wrapping an omental pedicle around the bronchus restored the blood supply to the ischemic donor bronchus and protected against anastomotic dehiscence.⁹ Recipient selection was also addressed, because most of the early attempts had been in acutely ill, often ventilator-dependent patients. The Toronto group reasoned that patients with end-stage respiratory failure from pulmonary fibrosis would provide the ideal physiologic conditions for single-lung transplantation. The increased resistance to both perfusion and ventilation of the native lung would preferentially direct perfusion and ventilation to the transplanted lung. On November 7, 1983, the first successful isolated lung transplant was performed in a 58-year-old man with pulmonary fibrosis.¹ Use of the omental flap and the withholding of steroids perioperatively are now mainly of historical interest. In the final analysis, it appears to be the attention to detail that this group practiced that led to the transplant's long-term success.

Patterson and colleagues used the en bloc double-lung transplant technique to extend the use of lung transplantation to patients with septic lung diseases and emphysema.¹⁰ The en bloc double-lung transplant, however, had several drawbacks: it was technically difficult, it required cardiopulmonary bypass (CPB), tracheal anastomotic ischemic complications were frequent, cardiac denervation occurred, and bleeding into the posterior mediastinum was troublesome because of poor operative exposure. To circumvent these problems, Pasque and colleagues¹¹ devised the technique of bilateral sequential lung transplantation. A transverse thoracosternotomy provided excellent exposure of the mediastinum and both pleural spaces. Recently, this incision was modified to avoid sternal division, when possible, to eliminate sternal wound complications.

Patients with emphysema were initially felt to be poor candidates for single-lung transplantation, because the overly compliant native lung would be prone to hyperinflation, resulting in mediastinal shift and compression of the transplanted lung. Despite this concern, successful single-lung transplantation for emphysema was reported in 1989 by Mal and colleagues.¹² Pasque and colleagues¹³ reported success with single-lung transplantation for patients with pulmonary hypertension.

The first applications of living related lobar transplants were reported by Starnes and colleagues.¹⁴ Split-lung techniques have been developed to allow a large left donor lung to be bipartitioned and the individual lobes transplanted bilaterally.¹⁵ In addition, the use of lungs from non-heart-beating donors has moved from the research realm to clinical reality.¹⁶ Most recently, the use of extended normothermic ex vivo lung perfusion has led to an increase in the percentage of donor lungs used for transplant by allowing for an objective assessment and subsequent repair (or rejection) of high-risk donor

lungs.¹⁷ Furthermore, when these lungs are transplanted, early outcomes are similar to those with conventionally selected and transplanted lungs.¹⁸

SELECTION

Recipients

General selection criteria for lung transplantation are listed in [Box 14-1](#) and disease-specific guidelines are listed in [Box 14-2](#), adapted from the most recent international guidelines for the selection of lung transplant candidates.¹⁹

Advanced recipient age is associated with decreased survival after lung transplantation.²⁰ Despite this, there has been an increase in lung transplants in patients over the age of 65. From 2006 through mid-2012, 10% of lung transplant recipients were older than 65 years and 3% were older than 70 years, an increase from 3% and 0.3%, respectively, from 2000 to 2005.²⁰ One study of 225 lung transplant recipients 70 years or older demonstrated similar survival to recipients aged 60 to 69 years.²¹

Absolute contraindications to lung transplantation are listed in [Box 14-3](#).¹⁹ A history of malignant disease within the prior 5 years generally prohibits lung transplantation. A potential exception is a patient with lung adenocarcinoma in situ or minimally invasive adenocarcinoma (formerly known as *bronchoalveolar carcinoma*). A recent study of 29 patients with bronchoalveolar carcinoma undergoing lung transplantation demonstrated that these patients have similar 30-day mortality and 5-year survival rates as patients undergoing lung transplantation for noncancer diagnoses.²² Interestingly, the presence of invasive tumor or lymph node metastases did not rule out the possibility of long-term survival.²² The patient with a recent extrathoracic malignancy deemed to be cured might be considered for transplant.

Previous thoracic surgery is not an absolute contraindication to lung transplantation, although it may complicate a transplant operation. Patients receiving high-dose corticosteroid therapy (≥ 20 mg prednisone) are not eligible for lung transplantation, because a well-documented negative influence on bronchial healing and susceptibility to postoperative infection has been demonstrated. However, low- or moderate-dose steroid therapy does not result in an increased incidence of bronchial anastomotic complications. Ventilator dependency is not an

BOX 14-1 Recipient Selection Criteria

- Clinically and physiologically severe disease
- Medical therapy ineffective or unavailable
- Substantial limitations in activities of daily living
- Limited life expectancy
- Adequate cardiac function without significant coronary disease
- Ambulatory, with rehabilitation potential
- Acceptable nutritional status
- Satisfactory psychosocial profile and emotional support system

BOX 14-2 Guidelines for Transplantation by Pulmonary Disease**CHRONIC OBSTRUCTIVE PULMONARY DISEASE**

- Patients with a BODE index* of 7 to 10 or at least one of the following:
 - History of hospitalization for exacerbation associated with acute hypercapnia ($\text{PCO}_2 > 50$ mm Hg)
 - Pulmonary hypertension or cor pulmonale, or both, despite oxygen therapy
 - $\text{FEV}_1 < 20\%$ predicted and either $\text{DLCO} < 20\%$ predicted or homogeneous distribution of emphysema

CYSTIC FIBROSIS AND OTHER CAUSES OF BRONCHIECTASIS

- Oxygen-dependent respiratory failure
- Hypercapnia
- Pulmonary hypertension

IDIOPATHIC PULMONARY FIBROSIS AND NSIP

- Histologic or radiographic evidence of usual interstitial pneumonia and any of the following:
 - $\text{DLCO} < 39\%$ predicted
 - 10% or greater decrement in FVC during 6 months of follow-up
 - A decrease in pulse oximetry below 88% during a 6-MWT
 - Honeycombing on high-resolution computed tomography (fibrosis score > 2)
- Histologic evidence of NSIP and any of the following:
 - $\text{DLCO} < 35\%$ predicted
 - 10% or greater decrement in FVC or 15% decrease in DLCO during 6 months of follow-up

PULMONARY ARTERIAL HYPERTENSION

- Persistent New York Heart Association class III or IV on maximal medical therapy
- Low (< 350 m) or declining 6-MWT
- Failing therapy with intravenous epoprostenol or equivalent
- Cardiac index < 2 L/min/m²
- Right atrial pressure > 15 mm Hg

*BODE index includes body mass index, degree of airflow obstruction (assessed by percent predicted FEV_1), degree of dyspnea (assessed by the modified Medical Research Council [MMRC] dyspnea scale), and exercise capacity (assessed by the 6-minute walk distance). The index increases as body mass index, FEV_1 , and distance walked decrease and as the MMRC scale increases.
 6-MWT, 6-minute walk test; DLCO , diffusing capacity of the lungs for carbon monoxide; FVC , forced vital capacity; *NSIP*, nonspecific interstitial pneumonia.

absolute contraindication to transplantation, but it has been identified as a risk factor for increased mortality. This is likely because of the debility associated with long-term ventilation.²⁰

All patients, except those with primary pulmonary hypertension (PPH) or Eisenmenger syndrome, participate in a monitored exercise rehabilitation program while awaiting transplantation. Virtually all patients experience an improvement in strength and exercise tolerance without any measurable change in pulmonary function. This improved endurance enables recipients to better

BOX 14-3 Absolute Contraindications to Lung Transplantation

- Malignancy within the last 2 years, with the exception of cutaneous squamous and basal cell carcinomas; the role of lung transplantation in patients with focal pulmonary adenocarcinoma in situ (formerly known as *bronchoalveolar carcinoma*)
- Untreatable advanced dysfunction of another organ system (heart, liver, kidney); coronary artery disease not amenable to percutaneous intervention or bypass grafting, or associated with significant impairment of left ventricular function, is an absolute contraindication to lung transplantation, but heart-lung transplantation could be considered in some cases
- Noncurable chronic extrapulmonary infection including chronic active viral hepatitis B, hepatitis C, and human immunodeficiency virus
- Significant chest wall or spinal deformity
- Nonadherence or inability to follow through with medical therapy or office follow-up
- Untreatable psychiatric or psychological condition associated with the inability to cooperate or comply with medical therapy
- Absence of a consistent or reliable social support system
- Substance addiction (alcohol, tobacco, or narcotics) that is either active or has been within the last 6 months

withstand the rigors of a transplant operation and subsequent recovery.

Lung allocation in the United States was previously based on time on the waitlist, regardless of medical urgency or deterioration in medical condition. This system was flawed because it favored recipients well enough to survive on the transplant list, whereas those who may have benefitted most risked death while waiting. An ideal system of organ allocation balances clinical necessity with the ability to recover from a transplant operation. The United Network for Organ Sharing (UNOS) Thoracic Organ Committee revised the listing algorithm by assigning each patient a lung allocation score (LAS) based on the immediate need for transplant and the probability of post-transplant survival. This led the UNOS, in 2005, to rearrange its waitlist for adult lung transplantation to one based on the LAS score. Details of the allocation system are found on the official Organ Procurement and Transplantation Network website.²³

The LAS score is calculated by estimating waitlist urgency, defined as the expected number of days that could be lived without a transplant (Box 14-4), and post-transplantation survival, defined as the expected number of days lived during the first year after transplantation (Box 14-5). The transplant benefit measure is then derived by subtracting the waitlist urgency from the post-transplantation survival to obtain the raw allocation score (calculated in days). This score is normalized to the LAS on a scale of 1 to 100. The highest scores are listed first for transplantation. Factors used to predict risk of death and posttransplantation survival are regularly reviewed by the Thoracic Organ Transplantation Committee and updated as needed.

BOX 14-4 Factors That Predict Risk of Death for Patients on the Transplant Waiting List

- Forced vital capacity
- Pulmonary artery systolic pressure
- Oxygen required at rest
- Age
- Body mass index
- Diabetes
- Functional status
- Six-minute walk distance
- Continuous mechanical ventilation
- Diagnosis

BOX 14-5 Factors That Predict Survival after Lung Transplantation

- Forced vital capacity
- Pulmonary capillary wedge pressure ≥ 20 mm Hg
- Continuous mechanical ventilation
- Age
- Serum creatinine level
- Functional status

Disease-Specific Guidelines

Obstructive lung disease, with and without α_1 -antitrypsin deficiency, is currently the most common indication for lung transplantation, accounting for 39% of the adult lung transplantations reported in the 2013 Registry of the International Society for Heart and Lung Transplantation (ISHLT).²⁰ The second most common indication for lung transplantation was interstitial lung disease, accounting for 24% of lung transplants.²⁰

Before being considered for lung transplantation, patients with obstructive lung disease should have maximization of medical therapy including bronchodilators and oxygen. Consideration should be given to lung volume reduction surgery (LVRS) in ideal patients (with hyperinflation, heterogeneous distribution of disease, forced expiratory volume in 1 second [FEV₁] of more than 20%, and normal PCO₂).²⁴ We have not found LVRS to be an ideal option in patients with α_1 -antitrypsin deficiency, because these patients typically have diffuse disease.²⁴ Preliminary LVRS does not jeopardize subsequent successful lung transplantation²⁵ and may provide benefit while delaying time to lung transplantation.²⁶ We favor a meticulous selection process in which both transplantation and volume reduction are considered, and the best option is selected for each patient. In general, in patients with obstructive lung disease, the FEV₁ should be less than 25% of predicted value, and not reversible, although most patients usually have an FEV₁ of less than 15% of predicted at the time of transplantation. Progressive deterioration as indicated by hypercarbia (PaCO₂ ≥ 55 mm Hg), increasing oxygen requirement (resting PaO₂ < 55 mm Hg), the development of secondary pulmonary hypertension, rapid decline of FEV₁, or frequent

life-threatening infections indicate decreased survival, suggesting the need for transplantation.¹⁹

Septic lung disease is another common indication for lung transplantation. Cystic fibrosis (CF) is a common inherited disorder resulting in diffuse bronchiectatic destruction of both lungs. Without transplantation, the overwhelming majority of patients die as a result of progressive respiratory failure in the second or third decade of life. As reported in the 2013 ISHLT Registry, CF is the second most common indication for bilateral-lung transplantation and the third most common indication for lung transplantation in general.²⁰ The most reliable predictors of mortality in CF patients include an FEV₁ of less than 30% predicted, elevated PaCO₂, requirement for supplemental oxygen, frequent admissions to the hospital for control of acute pulmonary infection, and failure to maintain weight.²⁷ At this stage of disease, patients with CF usually have a rapidly progressive downhill course. To offset this high waitlist mortality, some of these factors have been incorporated into the LAS.

Patients with septic lung disease or those with significant sputum production are evaluated with frequent sputum cultures to determine bacterial sensitivities. Inhaled high-dose aminoglycosides or colistin are frequently used in this population. Patients with multidrug-resistant organisms, especially pan-resistant *Burkholderia cepacia*, are considered high risk, and many centers consider this a contraindication to transplantation. Some studies have shown that early mortality after lung transplantation in patients with CF who have *B. cepacia* infection is significantly increased.^{28,29} However, a recent review found several studies that were clearly in favor of *B. cepacia*-infected or colonized CF patients being listed for lung transplantation, because there was no difference in survival nor mortality risk compared with noninfected patients.³⁰ Successful transplantation in these patients often requires the use of multiple combinations of intravenous antibiotics after in vitro synergy testing to guide antibiotic selection. If no susceptible antibiotic regimen is found on synergy testing, we do not proceed with transplantation.

The diagnoses of pulmonary fibrosis and restrictive lung disease include idiopathic pulmonary fibrosis (IPF), pulmonary fibrosis of other etiologies, sarcoidosis with elevated pulmonary artery pressures, and obliterative bronchiolitis (not re-transplant cases). The 2013 ISHLT Registry report indicated that IPF was the second most common indication for single-lung transplantation and the third most common for bilateral-lung transplantation.²⁰ In our experience, candidates for transplantation had classic restrictive findings on spirometry, with a mean forced vital capacity (FVC) of 1.35 L and an FEV₁ of 1.14 L.³¹ All used supplemental oxygen and demonstrated marked impairments in exercise tolerance. Moderate pulmonary hypertension is common in these patients. Patients with pulmonary fibrosis who require a transplant have been observed to have a rapid downhill course. The lung allocation score has been devised to recognize the medical urgency of these patients.

Before the 1990s, the outlook for patients with pulmonary arterial hypertension (PAH) was poor given a lack of medical therapeutic options; heart lung transplantation

was the only option for long-term survival.³² The introduction of intravenous epoprostenol in the early 1990s and a better understanding of the pathogenesis of PAH led to earlier diagnosis and implementation of effective medical therapy.³³ Over the past three decades, improved medical management of PAH has led to an improvement in pulmonary artery pressures and relief of symptoms in the majority of patients, as well as a decrease in the number of patients needing transplantation.³²⁻³⁴ Transplantation may be delayed as long as these patients remain clinically stable on vasodilator therapy. The current indication for transplantation is progressive deterioration despite optimal medical therapy. This is defined as New York Heart Association (NYHA) class III or IV, low (<350 m) or declining 6-minute walk test, failing therapy with intravenous epoprostenol or equivalent, right atrial pressure (RAP) greater than 15 mm Hg, and cardiac index <2 L/min/m².¹⁹ Since the implementation of the lung allocation score, the probability of transplantation for PAH is low, with an increased mortality on the waiting list compared with other indications for lung transplantation.³² Data from the Registry to Evaluate Early and Long-term PAH Disease Management (REVEAL) indicate that using a modified LAS score including a mean RAP of ≥14 mm Hg or a 6-minute walk distance ≤300 m would improve predictions of waitlist urgency for patients with PAH.³² Double-lung transplantation has become the operation of choice for PAH in most centers; heart-lung transplantation is rarely necessary for PAH because the right ventricle typically recovers rapidly after lung transplantation. In most centers, heart-lung transplantation is reserved for patients with PAH associated with congenital heart disease. However, patients with Eisenmenger syndrome with associated atrial or ventricular septal defect should be considered for double-lung transplantation and repair of the cardiac defect.

Donors

Rapid progress in the field of transplantation has resulted in a shortage of suitable allografts for all organs. This problem is particularly significant for lung transplantation, because only 15% of otherwise suitable organ donors have lungs satisfactory for transplantation, according to the criteria listed in [Box 14-6](#). Many conditions

resulting in brain death (e.g., trauma, spontaneous intracerebral hemorrhage) also lead to significant pulmonary parenchymal pathologic change because of lung contusion, infection, aspiration, or neurogenic pulmonary edema.

Satisfactory gas exchange is essential for donor lungs. This is confirmed by measuring a PaO₂ of greater than 300 mm Hg with an inspired oxygen fraction (FiO₂) of 100% and peak end-expiratory pressure (PEEP) of 5 cm H₂O. A PaO₂-to-FiO₂ ratio of 300 or greater indicates adequate gas exchange. A donor chest radiograph taken shortly before procurement must reveal clear lung fields. Bronchoscopic assessment at the donor institution often reveals mucopurulent secretions. This is common and is not a specific contraindication to lung transplantation if the donor is otherwise suitable. Bronchoscopic evidence of aspiration or frank pus in the airway, however, is a definite contraindication to transplantation of that lung.

The donor's medical history is obtained, with particular emphasis on and attention paid to the donor's age, cause of death, timing of death, smoking history, and prior thoracic procedures. Older donor age is associated with decreased survival after lung transplantation, and, in general, donors younger than 55 are preferred.²⁰ Despite this, according to the 2013 Registry of ISHLT, although young adults (18-29 years old) comprised 30% of lung donors, the use of lungs from donors older than 50 years old has increased over the past two decades.²⁰ Although a significant smoking history (≥30 pack-years) in the donor is a concern, it is not an absolute contraindication to the use of otherwise suitable donor lungs. In fact, a study from the UK demonstrated that although lungs from donors with a significant smoking history are associated with worse outcomes, the individual probability of survival is greater if those lungs are accepted than if they are declined and the patient waits for a potential transplant from a donor without a smoking history.³⁵ ABO blood type incompatibility between donor and recipient, human immunodeficiency virus positivity, active malignancy (outside the central nervous system), and active hepatitis infection remain absolute contraindications to donor lung procurement. Histocompatibility matching for human leukocyte antigens (HLAs) is not usually performed between donor and recipient before transplantation unless the patient has an elevated panel-reactive antibody or known HLA antibodies from prior sensitization.

Size matching between donor and recipient is an important consideration. An acceptable size match depends on the nature of the recipient's lung disease and the type of transplant anticipated. The most reliable method of size matching predicts donor and recipient lung volumes using standard nomograms based on age, sex, and height, and is used by all pulmonary function laboratories to predict lung volumes. In patients undergoing single-lung transplantation for obstructive lung disease, we try to place allografts with 15% to 20% greater volume than the recipient predicted lung volume. Implantation of a large allograft is easily achieved in a patient with obstructive lung disease because of the enormous size of the recipient pleural space. In patients with pulmonary fibrosis or pulmonary vascular disease,

BOX 14-6 Ideal Lung Donor Selection Criteria

- Age < 55 years
- No history of pulmonary disease
- Normal serial chest radiograph
- Adequate gas exchange: PaO₂ > 300 mm Hg, FiO₂ = 1.0, positive end-expiratory pressure = 5 cm H₂O
- Normal bronchoscopic examination
- Negative serologic screening for hepatitis B and human immunodeficiency virus
- Recipient matching for ABO blood group
- Size matching

however, the pleural spaces are reduced or normal in size, respectively. It is therefore inadvisable to use excessively oversized lungs in these patients. In patients undergoing bilateral-lung transplant, we prefer to match the donor lung volume to the lung volume or anticipated lung dimensions that the recipient would possess in the absence of lung disease. Oversizing a bilateral recipient may cause hemodynamic instability upon chest closure. Donor lungs that are substantially larger than the recipient's chest cavity but are otherwise usable should not preclude transplantation. We prefer to downsize the lungs by doing a lobectomy on the back table. If the size mismatch is noted after implantation, bilateral wedge resection, targeting the lingula and the right middle lobe, is carried out using stapling devices.

Certain circumstances allow for relaxation of the typically strict donor selection criteria. A minor degree of pulmonary infiltrate may be accepted in donor lungs being used for a bilateral transplantation. We analyzed 133 consecutive donor lungs and identified 37 with marginal quality, as judged by arterial blood gas analysis and radiographic assessment. The marginal donors provided postoperative function equivalent to those judged to be excellent.³⁶ Several recent studies have demonstrated no difference in post-lung transplant survival when using lungs from extended-criteria donors.^{37,38}

Novel techniques to optimize use of donor lungs have been introduced. Using the split-lung technique, the left lung of a large cadaveric donor is bipartitioned and the two lobes are used to perform a bilateral-lobar transplant in the smaller recipient. It requires significant expertise in lung transplantation, but it has been done successfully with good outcomes at certain institutions.^{15,39} Living lobar donors are also used to overcome the cadaveric lung donor shortage. Two healthy donors each donate one lobe. Donor right lower lobe and left lower lobe are implanted in the recipient on the respective sides.⁴⁰ Although we have acquired significant experience with this approach, we have not used this option in any patient since adoption of the lung allocation score system in 2005.

Another technique that is regaining popularity is the use of non-heart-beating donors.¹⁶ The lung is unique because it can tolerate warm ischemia for up to 1 hour. This is possible because the lung has a low metabolic requirement and is normally filled with well-saturated blood, and its alveoli are filled with oxygen.⁴¹ This ability of pulmonary parenchymal cells to continue aerobic cellular metabolism by relying on the oxygen in the alveoli make the lung potentially the ideal organ for transplantation after cessation of circulation, so-called "donation after cardiac death" (DCD). There are four types of DCD donors: Categories I (dead on arrival) and II (unsuccessful resuscitation) comprise the uncontrolled donors, and Categories III (awaiting cardiac arrest) and IV (cardiac arrest in brain-dead donors) consist of the controlled donors. Controlled DCD donors are the most common type. The largest series of DCD donors included 70 bilateral and 2 single-lung transplantation recipients.⁴² One- and 5-year survival in this study was 97% and 90%, respectively, and the incidence of grade 3 primary graft dysfunction was only 8.5% at 24 hours. Several other recent series have demonstrated comparable outcomes

between lung transplant recipients of DCD donors and brain dead donors.⁴³⁻⁴⁷ Despite this, DCD is only practiced by a few transplant centers.

The most recent development in the field of lung transplantation is ex vivo lung perfusion (EVLP). Steen and colleagues developed the first ex vivo perfusion system with the goal of using it to assess donor lung function in non-heart-beating donors; they described the first case report of successful transplantation of an unacceptable lung after ex vivo reconditioning.⁴⁸ Keshavjee and colleagues developed a strategy for successful long-term (12 hour) EVLP that would enable careful evaluation and potential repair of the donor lungs.⁴⁹ This strategy was made possible by adhering to several important concepts.⁵⁰ First, an acellular perfusate is used to avoid the problem of limited red blood cell life span; the lungs are oxygenated via the ventilator rather than the vasculature. Second, only 40% of the maximal cardiac output is used to perfuse the lungs thereby decreasing hydrostatic pressure and pulmonary edema without compromising perfusion. Finally, this group discovered that a left atrial pressure of 3-5 mm Hg is an important parameter to maintain. In a landmark study, the Toronto Lung Transplant Program group identified high-risk donor lungs and subjected these lungs to EVLP for 4 hours.¹⁸ The main outcome was primary graft dysfunction (PGD) at 72 hours. The incidence of PGD was 15% in the EVLP group (20 lungs) and 30% in the control group (116 lungs) and there was no difference in the secondary end points: 30-day mortality, bronchial complications, duration of mechanical ventilation, and hospital and intensive care unit (ICU) lengths of stay. Ultimately, it may be possible to treat donor lungs with medications to reduce pulmonary edema and inflammation or gene and cell therapy to prepare the lungs to deal with reperfusion and immunologic insults.⁵⁰

To ensure the most efficient transfer of data, the transplant network for the United States requires a complex computer system. UNet is a secure Internet-based transplant information database created by UNOS for the nation's organ transplant centers and organ procurement organizations to register patients for transplants, match donated organs to transplant candidates, and manage the critical data of all patients. In 2006, DonorNetSM was launched to increase the efficiency and accuracy of the organ placement process. It is a central electronic environment in which organ procurement coordinators send out offers of newly donated organs to transplant centers with compatible candidates. Organ offers can now be made to multiple transplant centers simultaneously, ensuring that organs can be matched and placed efficiently.

DONOR OPERATION

Procurement

Brain-Dead Donor

Once a candidate is determined to be a suitable donor for lung transplantation on the basis of history, chest radiograph, and arterial blood gas analysis, a flexible

bronchoscopy is done to ensure that there are no copious purulent secretions or signs of aspiration and to thoroughly suction the tracheobronchial tree.⁵¹ A small amount of purulent secretions that clears away with the initial suction is not a contraindication to procurement. Anatomic variations that may complicate implantation are noted. Clear and effective communication between the heart and lung procurement teams should be established. The sites of left and right heart venting, division of the left atrial cuff, and cannulation and division of the main pulmonary artery (PA) should be discussed and agreed upon.

Using a standard median sternotomy approach, the pericardium and both pleural spaces are widely opened. Recruitment of all atelectatic lung segments is done in situ using a sustained inflation pressure of 30 cm H₂O pressure. A compliance check is performed on the lungs by disconnecting the ventilator at end inspiration; this should result in a prompt deflation of the lungs. The lungs are manually palpated to rule out any unsuspected pathology. The pericardium is retracted with heavy silk sutures that are not tied, to allow access to both pleural spaces. At this point, we communicate with the implantation team about the quality of lungs and any concerns before proceeding.

The thoracic organ dissection begins by dissecting the aortopulmonary window in preparation for the aortic cross clamp. The main and right pulmonary arteries are separated from the ascending aorta. The superior vena cava (SVC) is dissected circumferentially to free it from all its mediastinal attachments. A heavy silk tie is passed around the SVC cephalad to the azygos vein and a Rommel tourniquet is loosely applied. A 2-0 silk tie is passed around the azygos vein and tied off about one-half centimeter away from its take off of the SVC. The SVC and the aorta are gently retracted, and the posterior pericardium is incised above the right PA, allowing access to the trachea. The plane around the trachea is developed using finger dissection. The Waterson interatrial groove is then carefully sharply dissected. This maneuver allows access to the left atrium for left ventricular venting and easier differentiation of cardiac and pulmonary left atrial cuffs when excising the heart and lungs.

After completion of the thoracic dissection and ensuring that abdominal organ procurement teams are ready, the donor is systemically heparinized (250 to 300 U/kg). The ascending aorta is cannulated with a routine cardioplegia cannula for cardiac preservation. A prolene U-stitch is placed near the pulmonary valve and a Sarns (Ann Arbor, MI) 6.5-mm curved metal cannula is placed into the main PA, with the tip pointing toward the PA bifurcation if the lungs only and not the heart are being procured. If both heart and lungs are being procured, the PA is cannulated at a minimum of 1.5 cm from the pulmonary valve, with the cannula tip pointing toward the pulmonary valve.

Using a fine needle, a 500- μ g bolus dose of prostaglandin-E₁ is injected directly into the PA; this may cause hypotension. Next, three maneuvers are done to decompress the heart before cross-clamping the aorta. First, the SVC silk tie is cinched down using the Rommel tourniquet. Second, a small incision is made in the left

atrium via the Waterson groove dissection, and a Yankauer suction is advanced across the mitral valve into the left ventricle. This incision will later be extended during the division of the left atrium into cardiac and pulmonary cuffs. Finally, the inferior vena cava (IVC) is transected with scissors. The aorta is then cross-clamped and cardioplegia initiated. The pulmonary preservation solution, 50 to 75 mL/kg of cold (4°C) Perfadex (Addmedica, Paris, France), is administered via gravity into the PA cannula. Ice slush is generously used to topically cool the heart and both pleural spaces. Gentle ventilation is continued to prevent atelectasis and homogeneously distribute the perfusate. Both lungs should blanch equally with the pulmoplegia infusion.

After completion of the cardioplegia and the ante-grade pulmonary flush, the cannulae are removed. The IVC is now freed posteriorly and dissected up to the level of the right atrium, ensuring that the right inferior pulmonary vein is not injured during this maneuver. Division of the left atrium ensues with the cooperation of the heart and lung teams. The left atrial incision begins halfway between the left inferior pulmonary vein and the atrioventricular (AV) groove (coronary sinus). This incision is extended in a plane parallel to the AV groove toward the base of the left atrial appendage on the left and toward the inferior edge of the IVC on the right. The left atrial incision is completed from inside the left atrium; all four pulmonary vein orifices can be visualized with preservation of optimal atrial cuff lengths on both the heart and lung blocks. An optimal residual atrial cuff should have a rim of left atrial muscle around each of the pulmonary vein orifices (Fig. 14-1). The SVC and azygos vein are transected. This is followed by division of the aortic arch vessels and the main PA at the site of cannulation. The heart is then passed off the field. Next, a Foley

FIGURE 14-1 ■ The heart is being explanted, leaving a rim of atrium around each pulmonary vein orifice. (From Sundaresan S, Trachiotis GD, Aoe M, et al: Donor lung procurement: assessment and operative technique. *Ann Thorac Surg* 56:1409-1413, 1993.)

catheter is used to deliver 250 mL of retrograde pulmonary flush via each of the pulmonary vein orifices, which often delivers residual blood and small clots out of the open PA bifurcation. Retrograde pulmonary perfusion results in improved oxygenation, higher compliance, and a lower extravascular lung water index in transplanted lungs in the experimental setting.⁵²

We then proceed with en bloc removal of the mediastinal contents. This technique avoids injury to the membranous trachea, pulmonary arteries, and pulmonary veins, and it preserves maximal soft tissue for collateral flow to the airway. At the level of the aortic arch vessels, the mediastinal tissues are divided down to the level of the trachea. The donor is then extubated and the trachea is divided sharply between two TA-30 staple lines (Fig. 14-2). We do not inflate the lungs before this maneuver. The proximal esophagus is divided using an Endo GIA linear stapler (Covidien, Boulder, Colo.). The remaining mediastinal tissue is divided straight back to the thoracic spine, and this organ bloc is gently lifted and dissected off of the spine to the level of the midthorax. Attention is then turned to the lower thorax. The pericardium is divided near its attachments to the diaphragm, taking care not to injure the lung parenchyma. The inferior pulmonary ligaments are mobilized and divided while protecting the lung by gently retracting each lower lobe cephalad. The distal esophagus is divided using an Endo GIA linear stapler. The remaining mediastinal tissue is again divided straight back toward the spine and then cephalad along the spine until the previous dissection is met, allowing removal of the mediastinal/lung bloc from the thoracic cavity.

If the lungs are to be used at separate institutions, they are separated on the back table. Otherwise, they are placed in three layers of plastic bags, with cold preservation solution, and transported on ice. Upon arrival in the recipient operating room, separation of the two lungs is

FIGURE 14-2 ■ Division of the trachea and esophagus before double-lung en bloc extraction and after removal of the heart. *Inset*, Division of the distal donor esophagus. (From Sundaresan S, Trachiotis GD, Aoe M, et al: Donor lung procurement: assessment and operative technique. *Ann Thorac Surg* 56:1409-1413, 1993.)

done in an ice slush bath. The donor esophagus and aorta are removed. The lungs are separated by division of the posterior pericardium, of the left atrium between the pulmonary veins, of the main PA at the bifurcation, and of the left bronchus close to the carina—in this order. A 15-blade is used to sharply cut across the left mainstem bronchus where it takes off of the carina; the carina is initially left with the right side. The donor bronchi are divided one ring proximal to the upper lobe orifice while minimizing proximal peribronchial dissection to preserve collateral flow. The right and left pulmonary arteries are dissected back to their first branches.

Non-Heart-Beating Donor

Our approach to non-heart-beating donors is similar to the heart-beating approach, with the exception that there is a significant time constraint. Gomez-de-Antonio and colleagues have described an alternative approach involving venoarterial extracorporeal membrane oxygenation and bilateral chest tube placement for topical cooling.⁵³

Atrial Cuff and Pulmonary Vein Injuries

Injuries most frequently involve the right inferior pulmonary vein and occur during the division of the left atrial cuff or division of the IVC. Pulmonary venous injuries can also occur as a result of excessive dissection of the inferior pulmonary ligament or unnecessary dissection of the atrial cuff within the pericardium. Unidentified, these injuries can lead to troublesome bleeding at reperfusion.

If the donor left atrial cuff is inadequate, or the superior and inferior veins are completely separated, a reconstructive salvage technique using donor pericardium has been described⁵⁴ (Fig. 14-3). It is estimated that as much as 2.7% of patients may need atrial cuff reconstruction, and Oto and colleagues have elegantly illustrated their techniques (Fig. 14-4).⁵⁵

Pulmonary Arteries

The right PA is more commonly injured because it courses behind the aorta and SVC. Because the right PA is substantially longer than the left, injury to this vessel under the aorta often does not require repair, and the artery is simply trimmed distal to the laceration. If necessary, repair is accomplished by simple suture or reconstruction using available donor pulmonary artery, azygos vein, or pericardium.

Congenital Bronchial Anomalies

A tracheal upper lobe bronchus, the most common anomaly, may be a segmental or a lobar bronchus. If the bronchus is a segmental bronchus, it may be either oversewn or reimplanted. If the entire right upper lobe bronchus arises as an abnormal tracheal bronchus, the options are donor right upper lobectomy, left single-lung transplantation, or incorporation of the bronchus intermedium and the aberrant right upper lobe bronchus into a modified anastomosis with the recipient bronchus.⁵⁶

RECIPIENT OPERATION

Anesthesia and Intraoperative Conduct

An experienced anesthesiologist who is adept in double-lumen tube management, bronchoscopy, and the use of

transesophageal echocardiography (TEE) is an invaluable part of the transplant team. Our patients undergo placement of an epidural catheter unless systemic heparinization for cardiopulmonary bypass is anticipated. If the indication for transplantation is septic lung disease, patients undergo therapeutic bronchoscopy and

suctioning via a large single-lumen endotracheal tube. Radial and femoral arterial lines, a PA catheter, a TEE probe, and heating blankets on both the operating table and lower body are routine. The patient is positioned supine with both arms tucked. Minimizing intravenous fluids without compromising end-organ perfusion may avoid or reduce postoperative respiratory insufficiency. We use vasopressors as indicated and avoid excessive volume resuscitation.

TEE is useful at various junctures in the operation.⁵⁷ Specifically, TEE monitoring is used to identify any intracardiac shunts, evaluate the right ventricle during PA clamping, determine the need for CPB based on classic signs of impending right ventricular decompensation, assess the arterial and venous anastomoses, and check for air in the left atrium. We use epoprostenol or nitric oxide (or both) for acute refractory pulmonary hypertension in the perioperative period. Inhaled nitric oxide is also indicated for poor oxygenation.

Implantation

Incisions

Bilateral anterolateral thoracotomy without sternal division is our preferred incision for bilateral sequential lung transplant.⁵⁸ The skin incision follows the inframammary crease at the level of the fourth intercostal space and extends from the lateral sternal edge to the anterior axillary line. The breast tissue is elevated and the pectoralis major muscle is divided. The chest cavity is entered in the fourth interspace. Bilateral internal mammary arteries are ligated and divided. Alternatively, the internal mammary arteries can be preserved if a 1-cm segment of costal cartilage of the fourth rib is resected at the sternal border, allowing upward mobility of the fourth rib when retracted. Further mobility for retraction is obtained by dividing the intercostal muscles from within the pleural space laterally to the paraspinal muscles. We place two chest wall retractors at 90-degree angles to one another (Fig. 14-5).

The *clamshell incision* (sternothoracotomy) involves connecting the bilateral anterolateral thoracotomy incisions across the midline by dividing the sternum (Fig. 14-6). This incision provides excellent exposure and requires the division of both mammary arteries. It is used to provide additional exposure when CPB is needed or when cardiomegaly and/or a relatively small thoracic cavity makes hilar exposure difficult. The sternum is reapproximated using two figure-of-eight #5 sternal wires.

A *median sternotomy* is used if the recipient is undergoing concomitant cardiac surgery. This approach may also be useful for women with large breasts that compromise the exposure obtained by anterolateral thoracotomy.

Posterolateral thoracotomy and anterolateral thoracotomy are used when the patient has significant cardiomegaly, which can make exposing the left hilum through an anterolateral thoracotomy difficult. This difficulty can be circumvented by transplanting the left lung via a left posterolateral thoracotomy incision and then repositioning the patient for a right anterolateral thoracotomy to transplant the right lung.

FIGURE 14-5 ■ Bilateral anterolateral thoracotomy. Two retractors are placed at right angles. (From Meyers BF, Patterson GA: Technical aspects of adult lung transplantation. *Semin Thorac Cardiovasc Surg* 10:213–220, 1998.)

The anterior axillary muscle-sparing thoracotomy incision, which may lead to improved chest wall and shoulder girdle mechanics, was initially described for single-lung transplant in recipients with chronic obstructive pulmonary disease.⁵⁹ The small anterior axillary thoracotomy is comparable with the more conventional posterolateral or clamshell incision in terms of operating times and ability to cannulate for central CPB.^{60,61}

Pneumonectomy

Before excision of the recipient lungs, the donor lungs should be separated and ready for implantation, and bilateral hilar dissection and adhesiolysis completed. This allows expeditious removal of the second lung, minimizing the amount of time that the newly implanted contralateral lung is exposed to the entire cardiac output. The lung with the poorer function, based on a preoperative ventilation perfusion scan, is transplanted first, because the other lung will more likely support single-lung ventilation.

During pneumonectomy, meticulous hemostasis is of prime importance in taking down pleural adhesions, particularly in patients with septic lung disease and prior thoracic procedures. The phrenic, vagus, and recurrent laryngeal nerves must be protected. During hilar dissection, the pulmonary arteries and veins are dissected beyond their first bifurcations to preserve the length of the main trunks. The right PA is transected approximately 1 cm beyond the truncus anterior branch and the left PA beyond the second branch to the left upper lobe. Vascular staplers are used on the central side of division, and ties are used peripherally. This maneuver downsizes the recipient PA, which may provide a better donor-recipient size match, and the ligated first branch of the recipient PA provides an anatomic landmark for orientation during the anastomosis. Next, the pulmonary veins

FIGURE 14-6 ■ The sternum has been divided for a clamshell incision that provides excellent exposure to the thorax. (From Lau CL, Patterson GA: Technical considerations in lung transplantation. *Chest Surg Clin North Am* 13:463–483, 2003.)

are divided at secondary branch points. The peribronchial tissue is divided, and bronchial artery bleeding is controlled with cautery or ligatures; bronchial arteries are often significantly enlarged in patients with septic lung disease. The bronchus is divided sharply just proximal to the upper lobe origin, and the lung is removed. All posterior mediastinal and posterior chest wall bleeding is controlled, because this is the only opportunity to access this area safely. Next, we prepare for implantation by exposing the hilum. The pulmonary artery is gently grasped in a clamp, freed centrally, and retracted anteromedially. The superior and inferior pulmonary veins are similarly grasped in clamps, the pericardium around them is widely opened, and the veins are retracted anteriorly. We are now ready for lung implantation.

Lung Implantation

The donor lung is covered with a cold lap pad and placed in a bed of ice slush into the thoracic cavity. We start with the bronchial anastomosis. Our preference is an end-to-end anastomosis using two 4-0 polydioxanone (PDS) sutures in a running fashion. A retraction suture (0 silk) is placed into the anterior aspect of the recipient bronchus to aid exposure. The anastomosis is started on the membranous portion of the airway in running fashion and carried around over the anterior cartilaginous portion with the second suture (Fig. 14-7). In case of significant size mismatch between the bronchi, the membranous portion is completed using a running 4-0 PDS suture, and the cartilaginous part is approximated with simple interrupted 3-0 VICRYL sutures (Ethicon Endo-Surgery, Cincinnati, Ohio; Fig. 14-8). The peribronchial tissue on the donor and recipient sides is used to cover the anterior aspect of the anastomosis to offer some protection to the overlying vascular anastomoses in case of bronchial anastomotic breakdown. End-to-end airway anastomosis is superior to the telescoped anastomosis technique.⁶²

Next, a vascular clamp is placed as proximal as possible on the recipient PA and the staple line resected. The donor and recipient PAs are trimmed to prevent excessive length and possible kinking, and an end-to-end

FIGURE 14-7 ■ Retraction on the pulmonary artery and pulmonary vein stumps provides exposure for the airway anastomosis. The bronchial anastomosis is being performed with 4-0 polydioxanone (PDS) suture. (From Meyers BF, Patterson GA: Technical aspects of adult lung transplantation. *Semin Thorac Cardiovasc Surg* 10:213–220, 1998.)

anastomosis is fashioned using a continuous 5-0 polypropylene stitch, using precise small bites to prevent anastomotic stricture (Fig. 14-9).

The pericardium is then opened circumferentially around the pulmonary vein stumps. The vein stumps are then retracted laterally and a Satinsky-type clamp is placed centrally on the recipient's left atrium. The recipient pulmonary venous stumps are amputated, and the two openings connected to create the atrial cuff. The anastomosis is fashioned with continuous 4-0 polypropylene suture. Stitches are placed via a mattress technique, which achieves intima-to-intima apposition and excludes potentially thrombogenic atrial muscle (Fig. 14-10).

The last few sutures of the venous anastomosis are left loose, the lung is partially inflated, and the PA clamp is released momentarily. This maneuver flushes air and perfusate out of the lung. The left atrial clamp is then opened

FIGURE 14-8 ■ The anterior wall of the bronchial anastomosis is performed with interrupted 3-0 Vicryl suture when a significant size mismatch is present. (From Meyers BF, Patterson GA: Technical aspects of adult lung transplantation. *Semin Thorac Cardiovasc Surg* 10:213–220, 1998.)

FIGURE 14-9 ■ The pulmonary artery anastomosis is fashioned using a running 5-0 polypropylene suture. (From Meyers BF, Patterson GA: Technical aspects of adult lung transplantation. *Semin Thorac Cardiovasc Surg* 10:213–220, 1998)

to completely de-air the atrium. The atrial suture line is pulled up tight and tied down. All clamps are removed.

If the operation is being done without CPB, it is important to stabilize the patient after the first lung is implanted. Pulmonary hypertension may result from hypercarbia that is corrected with a period of dual-lung ventilation. Using this maneuver, CPB for implantation of the second lung can often be avoided.

The pleural spaces are drained with two 24-Fr Blake drains (Ethicon, Somerville, N.J.) in each pleural space, one placed apically and one along the diaphragm. If significant postoperative bleeding is expected, two 28-Fr conventional chest tubes are preferred over Blake drains. The sternum is reapproximated with two figure-of-eight #5 sternal wires. The ribs are reapproximated with heavy interrupted figure-of-eight monofilament nonabsorbable suture. The chest wall is closed in layers.

A flexible bronchoscopy is done after exchanging the double-lumen tube for a single-lumen tube to evaluate

FIGURE 14-10 ■ A large Satinsky clamp is placed centrally across the left atrium. Both vein stumps are amputated, and the bridge between is connected to create a left atriotomy suitable for anastomosis. (From Patterson GA: Bilateral lung transplant: indications and technique. *Semin Thorac Cardiovasc Surg* 4:95–100, 1992.)

the airway anastomoses and remove blood and secretions. The patient is now transported, intubated, to the ICU.

Cardiopulmonary Bypass

We use CPB selectively in our patients. It is, however, indicated for children, small-statured patients when a double-lumen tube cannot be placed, lobar transplants, concomitant intracardiac procedures, and most patients with pulmonary hypertension. CPB is also indicated if at any point during the operation the patient develops refractory hypoxemia, hypercarbia, pulmonary hypertension, or hemodynamic instability. Difficult exposure is another indication for CPB. This is typically seen in patients with idiopathic pulmonary fibrosis who have a small pleural space with the heart shifted to the left, making exposure of the left hilum difficult (Fig. 14-11). A traction suture in the fibrous portion of the diaphragm, brought extracorporeally through a planned chest tube site, can improve exposure. Inadequate exposure of the left hilum is sometimes the only indication for CPB. We have also used the Urchin heart-positioning device (Medtronic, Minneapolis, MN) to improve exposure in these situations (Fig. 14-12).⁶³

When CPB is used electively, we do most of the dissection before systemic heparinization. Standard aortic cannulation is carried out, and a two-stage venous cannula is introduced via the right atrial appendage. We avoid the use of pump suckers. After implantation of the first lung, the left atrium is de-aired and the venous clamp removed. This also allows the placement of an atrial clamp for venous anastomosis on the contralateral side.

FIGURE 14-11 ■ Axial computed tomographic image from a patient with idiopathic pulmonary fibrosis shows a markedly diminished left pleural space with the mediastinum shifted to the left. This finding mandates the use of cardiopulmonary bypass for adequate exposure.

FIGURE 14-12 ■ An apical suction device is in place, lifting the apex of the heart and improving exposure to the left hilum. (From Lau CL, Hoganson DM, Meyers BF, et al: Use of an apical heart suction device for exposure in lung transplantation. *Ann Thorac Surg* 81:1524–1525, 2006)

POSTOPERATIVE MANAGEMENT

Ventilation

Patients are transported to the ICU and are ventilated using standard techniques. Tidal volumes of 7 to 10 mL/kg are usually sufficient. The FiO_2 is adjusted to keep the PaO_2 greater than 70 mm Hg, and PEEP of 5 to 7.5 cm H_2O is used in most patients. Frequent arterial blood gas analyses are performed. After an initial period of

evaluation, if the patients are hemodynamically normal and have no significant bleeding, and gas exchange is adequate, ventilator weaning is started. Patients are extubated according to standard criteria for gas exchange and respiratory mechanics. Most patients are extubated within 24 to 48 hours of transplantation after standard intermittent mandatory ventilation or pressure-support weaning. Before extubation, patients undergo bronchoscopy to ensure adequate clearance of secretions. This standard management is applied in all bilateral-lung transplant recipients and single-lung recipients undergoing transplantation for pulmonary fibrosis.

After single-lung transplantation for emphysema or pulmonary vascular disease, patients are managed using a different approach.⁶⁴ Preventing hyperinflation of the native lung and compression of the newly implanted lung are the main goals in patients with emphysema. This is accomplished by avoiding the use of PEEP and using lower tidal volumes. If air trapping occurs in the native lung, it leads to high airway pressures, inadequate removal of carbon dioxide, and hypotension from decreased venous return to the heart. This sometimes requires volume reduction of the native lung by lobectomy or even pneumonectomy.^{65,66}

In single-lung recipients with pulmonary vascular disease, we use a prolonged period (48–72 hours) of elective ventilation. The patient is positioned to keep the native lung dependent to maintain inflation and appropriate drainage of the transplanted lung. Tidal volumes are standard, but a higher PEEP of 7.5 to 10 cm H_2O is applied. If early graft dysfunction, rejection, or infection occurs, leading to a prolonged period of mechanical ventilation, tracheostomy should be done early in the postoperative course.

Fluid Management

In the early postoperative period, the Swan-Ganz catheter and daily weight measurement provide objective assessment of fluid status. The patients often return from the operating room with a significant positive fluid balance. Diuretics are used aggressively during the early postoperative period. Sometimes, patients undergoing single-lung transplantation for PPH develop hemodynamic instability if the filling pressures on the right side of the heart are excessively reduced, and these patients may require somewhat higher filling pressures.

General Care

Postoperatively, a quantitative lung perfusion scan to assess graft flow is done only if there are any major concerns. If a lobar or greater perfusion defect is appreciated, further interrogation for the cause should be undertaken either by catheterization or operative exploration. Aggressive clearance of airway secretions and inhalation of bronchodilators are required postoperatively. Early and constant involvement of the physical therapy team ensures that transplant recipients are out of bed to chair, walking with assistance, and using the treadmill or exercise bike as soon as possible.

IMMUNOSUPPRESSION

Immunosuppression after solid organ transplantation was revolutionized by the introduction of cyclosporine in the 1980s. Immunosuppression for lung transplantation is used for induction, maintenance, and treatment for rejection.

Induction therapy is controversial. High-dose methylprednisolone is routinely administered intraoperatively before reperfusion. However, there is no consensus on the routine use of induction immunosuppression.⁶⁷ Potential benefits include lower rates of acute rejection, protection from nephrotoxicity as a result of delayed introduction of a calcineurin inhibitor, and a decrease in bronchiolitis obliterans syndrome (BOS). Disadvantages are the higher risk of infectious complications and posttransplantation malignancies. Practice patterns vary significantly, and approximately 50% of patients undergoing lung transplantation receive induction immunosuppression.

Two types of induction immunosuppression agents are available: antithymocyte globulin and interleukin-2 receptor (IL-2R) antagonists.⁶⁷ Antithymocyte globulin is a formulation of polyclonal antibodies directed against T- and B-lymphocyte cell-surface antigens. In the United States, two types are available, Thymoglobulin (Genzyme, Cambridge, Mass.), derived from rabbits, and Atgam (Pfizer, New York, N.Y.), derived from horses. The animals are injected with human thymic cells or lymphocytes, leading to the formation of anti-human antibodies that are then isolated, purified, and used for induction therapy. IL-2R antagonists are humanized monoclonal antibodies directed against the IL-2 receptor on activated T cells, thereby interfering with T cell proliferation. Basiliximab (Simulect; Novartis Pharma, East Hanover, N.J.) is currently the only IL-2R antagonist used for induction therapy. This agent is generally well tolerated and is not associated with an increased incidence of post-transplant infections.⁶⁸

For maintenance therapy, the majority of lung transplant patients are placed on a three-drug regimen, consisting of a calcineurin inhibitor, an antimetabolite, and a low-dose corticosteroid. On a case-by-case basis, a mammalian target of rapamycin (mTOR) inhibitor may be used instead of either the calcineurin inhibitor or the antimetabolite. Tacrolimus (Prograf; Astellas Pharma, Northbrook, Ill.) is a calcineurin inhibitor that suppresses the transcription of IL-2, inhibiting the proliferation of T cells; it is 10 to 100 more times more effective at inhibiting T cell activation than cyclosporine. Mycophenolate fofetil (MMF) (Cellcept; Genentech, South San Francisco, Calif.) is an antimetabolite that noncompetitively blocks an enzyme in the purine synthesis pathway. Sirolimus (Rapamune; Pfizer, New York, N.Y.) is an mTOR inhibitor similar in structure to tacrolimus and binds the same cytosolic immunophilin, but this complex binds mTOR downstream from IL-2 in the T cell activation cascade. mTOR inhibitors should not be used until wounds and anastomoses are completely healed because of several reports of airway dehiscence in the early postoperative period.^{69,70} Everolimus (Zortess; Novartis) is a newer mTOR inhibitor with improved bioavailability and a similar side-effect profile. Most programs give

moderate-dose corticosteroid therapy (methylprednisolone, 0.5-1 mg/kg per day intravenously) for several days before starting an oral dose of prednisone 0.5 mg/kg per day. At both 1 and 5 years after transplantation, tacrolimus is the most common calcineurin inhibitor used and MMF the most common antimetabolite.⁷¹

INFECTION PROPHYLAXIS

We routinely administer broad-spectrum antibiotics (usually cefepime and vancomycin) for several days after transplantation. Results from donor and recipient airway cultures are used to adjust this empiric regimen. In patients with CF, aerosolized colistin or tobramycin is added, and special emphasis is placed on coverage for *Pseudomonas*.

Cytomegalovirus (CMV) reactivation in lung transplant recipients has been associated with CMV pneumonitis and gastrointestinal disease, as well as increased risk for development of BOS. The risk of development of CMV-related complications after lung transplantation is highly dependent on the CMV status of both the donor and the recipient, with donor-positive/recipient-negative at highest risk.⁷² A recent randomized controlled trial demonstrated that extending prophylaxis with valgancyclovir from the standard 3 months to 12 months after transplantation decreased the incidence of CMV disease from 32% to 4%.⁷³ During a mean follow-up of almost 4 years, extended-course CMV prophylaxis provided a sustained protective benefit over short-course prophylaxis with a lifetime CMV incidence of 12% versus 55%, respectively.⁷⁴ For mismatched recipients, we administer prophylactic therapy for 3 to 6 months. Otherwise, we use a preemptive treatment approach, where recipients are screened weekly by polymerase chain reaction (PCR) for CMV in the blood, and treatment is initiated if the PCR test becomes positive. For the first year after transplantation, we also routinely prescribe acyclovir (unless the patient is on ganciclovir or valganciclovir) for herpes simplex prophylaxis.

Aspergillus is the most common cause of invasive fungal infection in lung transplant recipients. Therefore, many transplant centers use routine antifungal prophylaxis. A recent meta-analysis evaluated the available literature to compare the development of invasive aspergillosis (IA) and colonization with and without fungal prophylaxis.⁷⁵ The results were that 19 of 235 (8.1%) and 28 of 196 (14.3%) developed IA in the prophylaxis and no-prophylaxis groups, respectively (relative risk 0.36, 95% confidence interval 0.05-2.62). There was no significant reduction in either IA or *Aspergillus* colonization with prophylaxis.

Lifelong *Pneumocystis jiroveci* pneumonia prophylaxis is started 3 weeks after transplantation. Our current strategy includes Bactrim DS (Roche Laboratories/Genentech, South San Francisco, Calif.) three times per week. One study of *Pneumocystis jiroveci* pneumonia in solid organ transplant recipients demonstrated that the highest incidence of *Pneumocystis* pneumonia occurred among lung transplant recipients and that there was no decrease in the incidence beyond 1 year as was seen with other types

of solid organ transplantation.⁷⁶ Therefore, lifelong prophylaxis is recommended. Alternative agents, such as monthly application of inhaled pentamidine, are administered when there is an allergy to sulfa medications.

As part of the frequent bronchoscopies performed in these patients, we routinely obtain samples from the bronchoalveolar lavage (BAL) for cytology, Gram stain, KOH test (potassium hydroxide), acid-fast bacilli stain, and immunostains for respiratory viruses, herpes simplex virus, and CMV. In addition, bacterial, mycobacterial, fungal, and viral cultures are obtained.

It is difficult to distinguish infectious pulmonary problems from rejection in the early posttransplantation lung recipient using radiographic, clinical, and physiologic criteria. This has led to the frequent use of fiberoptic bronchoscopy in these patients. BAL and transbronchial biopsies are done to examine for opportunistic infection and evidence of rejection, respectively. These studies are routinely performed at 2 to 3 weeks; at 2, 3, 6, and 12 months; and annually thereafter.

COMPLICATIONS

Technical Problems

With increasing experience, the technical aspects of lung transplantation have become more sophisticated and reproducible. However, as with any major operation, technical complications may occur perioperatively. Perioperative hemorrhage may be related to a large raw surface that is created after explantation from a patient with septic lung disease or one who has undergone previous pleurodesis. CPB usually exacerbates this problem. In addition to meticulous attention to stopping all surgically correctable bleeding, we aggressively correct any coagulopathy with blood products and use recombinant factor VII as needed. In this situation, we delay final chest closure and proceed to the ICU after approximating the skin and applying a transparent sterile dressing. Final chest closure is usually possible within the next 24 to 48 hours. This strategy does not increase the incidence of wound complications.⁷⁷

A technically unsatisfactory bronchial anastomosis is easily identified in the operating room during postimplantation bronchoscopy. Inadequate anastomotic caliber mandates immediate surgical revision. Pulmonary arterial anastomotic compromise manifests as persistent pulmonary hypertension and unexplained hypoxemia. Intraoperative TEE can be used to assess flow through the anastomoses intraoperatively. A nuclear perfusion scan performed immediately postoperatively will demonstrate less-than-anticipated flow to the affected side. The gold standard for studying the PA anastomosis is contrast angiography, which can additionally look for a gradient across the anastomosis. A gradient of 15 to 20 mm Hg may be found, especially in single-lung recipients, in whom most cardiac output is directed to the transplanted lung, or in bilateral recipients with a high cardiac output. The need for anastomotic revision is dictated by the clinical situation. Significant reduction in flow in the appropriate clinical setting indicates surgical correction,

because the donor bronchus depends entirely on pulmonary arterial collateral flow. Pulmonary venous anastomotic compromise can be technical or may be caused by a clot causing compression in the setting of hemorrhage. Similarly, TEE and contrast angiography, with close attention to the venous phase, will identify the problem. Sometimes, surgical exploration is necessary to confirm the diagnosis and repair the problem.

Primary Graft Dysfunction

Primary graft dysfunction develops in as much as 25% of lung transplant recipients.^{78,79} Mortality from PGD is as high as 30% and is the main cause of mortality in the perioperative period. The major diagnostic criteria for PGD are a decreased PaO₂-to-FiO₂ ratio in the first 48 hours after transplantation, and the presence of pan-lobar alveolar infiltrates on postoperative chest radiographs (Fig. 14-13). The ISHLT devised a grading system for primary graft dysfunction based on these criteria (Table 14-1).⁸⁰

Ischemia-reperfusion injury accounts for most cases of primary graft dysfunction (see Fig. 14-13). Other suspected causes include donor lung pathologic conditions

FIGURE 14-13 ■ **A**, Chest radiograph showing diffuse consolidation typical of ischemic reperfusion injury. The right lung was implanted first, which explains the increased injury appreciated on this side. **B**, Radiograph of the same patient after complete recovery.

TABLE 14-1 Grading System for Primary Graft Dysfunction

Grade	PaO ₂ /Fio ₂	Radiographic Infiltrates
0	>300	Absent
1	>300	Present
2	200-300	Present
3	<200	Present

From Christie JD, Carby M, Bag R, et al: Report of the ISHLT Working Group on Primary Lung Graft Dysfunction part II: definition. A consensus statement of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant* 24:1454-1459, 2005.

such as aspiration, infection, or contusion. The pathogenesis of PGD begins with the pathophysiologic changes that occur in the donor after brain death; it continues during the cold ischemia time period and then during reperfusion.⁸¹ The ischemia-reperfusion injury generates reactive oxygen species that go on to injure the pulmonary endothelium and epithelium. This injury leads to capillary leak, pulmonary edema, and decreased lung compliance that manifests as hypoxia and bilateral infiltrates on chest radiograph. In addition, macrophages in the donor lungs initiate an inflammatory cascade that leads to the release of mediators that then recruit and activate recipient leukocytes. Elevated recipient pulmonary artery pressure and prolonged ischemic time have been consistently identified as strong risk factors for the development of PGD.

Primary graft dysfunction is managed with aggressive cardiopulmonary support in the ICU. Lung protective ventilation strategies, diuresis, inhaled nitric oxide,⁸² and aerosolized prostacyclin⁸³ are used. In most patients, PGD resolves over several days of intensive care support, and they obtain satisfactory long-term allograft function.⁷⁹ ECMO support is used if conservative management is unsuccessful. In a review of our experience with 983 lung transplant recipients, 47 required ECMO for PGD during the immediate postoperative phase. ECMO was used in 9.7% of pediatric and 2.8% of adult lung transplant recipients.⁷⁹ Only 38% of patients who needed ECMO survived to discharge from the hospital. Eleven patients underwent retransplantation for PGD. There is a direct relationship between the severity of PGD and the development of BOS.⁸⁴

Infectious Complications

Infectious complications are a major cause of posttransplant morbidity and mortality. PGD and non-CMV infection are the major causes of death within the first year after transplant.⁸⁵ After the first year, the most common causes of death are BOS and non-CMV infection.

Bacterial

Gram-negative organisms are the most common cause of bacterial pneumonia, with *Pseudomonas aeruginosa* being the most frequent, followed closely by *Staphylococcus*

aureus.⁸⁶ Patients infected with *Burkholderia cenocepacia* have a sixfold higher risk of death at 1 year compared with patients infected with *Burkholderia cepacia complex*, and they have an eightfold higher risk than patients without *Burkholderia* infection.⁸⁵ Patients with CF need to be carefully evaluated before lung transplantation to determine whether *Burkholderia* spp. are present. Typical symptoms of pneumonia such as fever and cough are commonly masked by immunosuppressive therapy. Therefore, a thorough work-up in all lung transplant recipients with deteriorating lung function regardless of symptoms is mandatory. This includes a chest radiograph, complete blood cell count, bronchoscopy with BAL, and, possibly, transbronchial biopsies. Empiric antibiotic treatments for pneumonia should cover for methicillin-resistant *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and atypical bacterial infections.

Lung abscess is sometimes encountered in lung transplantation recipients, and patients with CF are susceptible to having multifocal lung abscesses resulting from inhalation of organisms colonized from an upper airway or sinus infection. The care of these patients is the same as it is for any other patient with lung abscess. Broad-spectrum antibiotic therapy is initiated, and bronchoscopy is done to ensure that there is no airway obstruction.

Viral

Cytomegalovirus disease is the most common postoperative infectious complication in lung transplant recipients (Fig. 14-14).^{85,86} It occurs in as much as one-third of transplant patients in the first year.⁸⁶ Because the lung can harbor high latent CMV loads, the incidence of CMV infection is higher after lung transplantation than after transplantation of other solid organs. The greatest risk of CMV infection occurs when a CMV⁺ recipient is transplanted with lungs from a CMV-positive donor. Therefore, most programs match seronegative donors with seronegative recipients. In addition, CMV may predispose a patient to the development of chronic allograft rejection. CMV also leads to further immunosuppression, such that patients are at an increased risk for other opportunistic infections and posttransplant lymphoproliferative disease.⁸⁷ The diagnosis of CMV infection (viral replication) at our institution is based on a positive PCR test on a blood sample, whereas the presence of cytomegalic cells (CMV inclusion bodies or positive immunoperoxidase stain) in tissue biopsies is considered indicative of CMV disease (CMV infection with symptoms) (see Fig. 14-14). If symptoms are present, patients are treated with intravenous ganciclovir or oral valganciclovir for at least 1 week after viral replication is no longer detectable.⁸⁵ CMV immunoglobulin can be given to patients who do not respond to standard antiviral treatment.

Although less common, non-CMV viral respiratory tract infections have been reported.^{88,89} These include herpesvirus, respiratory syncytial virus, parainfluenza virus, influenza virus, and adenovirus. These infections have also been linked to later development of chronic allograft rejection.^{90,91} Treatment includes supportive care and antiviral therapy.

FIGURE 14-16 ■ Histopathologic examination of acute rejection (*arrow*; hematoxylin and eosin stain, original magnification $\times 20$).

Fungal

Candida albicans is commonly isolated after transplantation; it usually represents colonization, but it may also be invasive.⁸⁶ These infections may be symptomatic or may be discovered on surveillance bronchoscopy. Candidal infections are most commonly associated with airway anastomotic complications.^{92,93} They can be treated with a combination of systemic and inhaled amphotericin B and fluconazole (some species are resistant).

The most frequent cause of significant fungal infection after transplantation is *Aspergillus* (Fig. 14-15). More commonly, however, *Aspergillus* spp. growing in sputum or BAL cultures represents colonization (see Fig. 14-15). Colonization is a risk factor for invasive disease, but only a fraction of colonized patients develop more serious infections.⁹⁴ *Aspergillus* infections are classified as either localized airway infection or invasive disease. Invasive disease is further subclassified as tracheobronchitis, invasive pulmonary aspergillosis, and disseminated aspergillosis. Aspergillosis tracheobronchitis tends to localize to the bronchial anastomoses. This can result in erosion involving the adjacent pulmonary artery, causing massive hemoptysis and death. Overall mortality for patients with invasive pulmonary aspergillosis or disseminated disease approaches 60%.⁹⁵ In less severe cases, it increases the

risk of airway complications including stenosis and bronchomalacia.⁹⁶ Voriconazole is the mainstay treatment for invasive aspergillosis; parenteral lipid formulations of amphotericin B is the second-line therapy. Prevention of aspergillosis involves infection-control measures such as wearing masks while near areas of hospital construction, as well as avoiding gardening, compost, and other outdoor exposures. Once *Aspergillus* sp. has colonized the airways, it is difficult to clear.

Acute Rejection

Acute rejection is seen more commonly after lung transplantation than after any other solid organ transplant (Fig. 14-16).⁹⁷ Although it is an uncommon cause of mortality, it is associated with the development of chronic rejection. The majority of episodes of acute rejection occur early in the postoperative period, and the incidence steadily declines after the first 3 months.⁹⁸⁻¹⁰⁰ Between July 2004 and June 2012, one-third of adult lung recipients experienced at least one episode of acute rejection between discharge and 1-year follow-up.²⁰

Patients with symptomatic episodes of acute rejection present with dyspnea, hypoxemia, low-grade fever, and moderate leukocytosis, which can be difficult to differentiate from infection. The chest radiograph often shows

diffuse, perihilar interstitial infiltrates; however, episodes occurring after the first month may appear as a normal chest radiograph. Episodes of acute rejection may also present with a decrease in lung function: 10% or greater decline in baseline FEV₁ or FVC. Bronchoscopy with transbronchial biopsy is used to confirm the diagnosis and rule out infection. Acute rejection is present if there is perivascular or peribronchial mononuclear inflammation. A grading system based on histologic criteria for classification of pulmonary transplant rejection was revised by the ISHLT in 2007 (Table 14-2).¹⁰¹

Acute rejection is usually treated with intravenous methylprednisolone, 10 to 15 mg/kg per day for 3 to 5 days. Most commonly, there is dramatic improvement in symptoms and radiographic findings within 8 to 12 hours; this is followed with a tapered steroid dose over 2 to 3 weeks. Baseline immunosuppression is reevaluated with recurrent acute rejection. We repeat bronchoscopy in 3 to 6 weeks to confirm an appropriate response to therapy. In approximately one-third of cases, persistent acute rejection is detected at follow-up.¹⁰² For refractory acute rejection, a trial of cytolytic therapy is often initiated.¹⁰³ Other therapies have included aerosolized cyclosporine,¹⁰⁴ alemtuzumab,¹⁰⁵ methotrexate,¹⁰⁶ extracorporeal photopheresis,^{107,108} and total lymphoid irradiation.¹⁰⁹ Despite the introduction of new immunosuppressant agents in the maintenance regimens of lung transplant recipients, none has been associated with a clear reduction in acute rejection.^{110,111}

Airway Complications

With standard methods of implantation, the donor bronchus is rendered ischemic as the systemic bronchial circulation is interrupted. The donor bronchus relies on collateral pulmonary arterial flow during the first few days after transplantation. Anastomotic complications

resulting from airway ischemia include infection, dehiscence, stenosis, and malacia. The reported incidence of these complications is 7% to 14%, although improvements in anastomotic techniques, pulmonary preservation, and care in preserving collateral circulation during the donor operation have decreased the incidence.¹¹²⁻¹¹⁴

In a review of our experience at Washington University in St. Louis, Missouri, the incidence of airway complications was associated with the time period during which the transplantation was performed. The incidence of airway complications during the initial period, from 1988 through 1993, was almost 16%; this decreased to less than 10% during later time periods. Importantly, airway complications did not seem to have an adverse impact on overall survival.⁷⁹

From a technical standpoint, a shortened donor bronchial length (one ring proximal to the upper lobe takeoff) reduces the length of the donor bronchus that is dependent on collateral flow. Peribronchial tissue on the donor bronchus is preserved during preparation of the lung. Telescoping the bronchial anastomosis has not been shown to reduce the rate of airway complications, and we do not use the telescoping technique unless we encounter a significant size mismatch between donor and recipient. Improved preservation techniques have also resulted in increased bronchial viability after transplantation. Post-transplantation pulmonary parenchymal pathology also compromises collateral flow, rendering the ischemic donor bronchus at increased risk for necrosis and dehiscence. Therefore, pulmonary allograft preservation and adequate postoperative pulmonary blood flow are important. Surprisingly, laboratory evidence points to the beneficial role of steroids in bronchial revascularization and epithelial regeneration.^{115,116}

Postoperative surveillance bronchoscopy leads to early identification of anastomotic complications. Computed tomography (CT) is a useful diagnostic tool for the evaluation of documented or suspected donor airway complications. Patients with late airway stenoses have symptoms of dyspnea, wheeze, or decreased FEV₁. Bronchoscopic assessment confirms the diagnosis.

Failure of Normal Bronchial Healing

Sometimes patchy areas of superficial necrosis of donor bronchial epithelium are seen. These areas are of no concern and ultimately heal. Minor degrees of bronchial dehiscence are also of little long-term consequence. Membranous wall defects typically heal without airway compromise, whereas cartilaginous defects usually result in some degree of late stricture. Significant dehiscence (>50% of the bronchial circumference) may result in compromise of the airway. This problem should be managed expectantly using laser or mechanical débridement of the area to maintain a patent airway. A stent can be placed only if the distal main airway remains intact. A significant dehiscence sometimes results in direct communication with the pleural space, resulting in pneumothorax and a significant air leak. If the lung remains completely expanded and the pleural space is evacuated, however, the leak will ultimately seal, and the airway may heal without significant stenosis.¹¹⁷

Similarly, a dehiscence may communicate directly with the mediastinum, resulting in mediastinal emphysema. If the lung remains completely expanded and the pleural space is filled, adequate drainage of the mediastinum can be achieved by placing a drain in close proximity to the anastomotic line by mediastinoscopy. This step will also lead to healing of the anastomosis, often without stricture.

Surgical revision of the anastomosis is possible only if an adequate length of donor airway is available for resuturing. This procedure is rarely possible, however, if the donor bronchus was cut to an appropriately short length at the time of the initial procedure. Massive dehiscence of the airway with uncontrolled leak or mediastinal contamination has been treated by retransplantation.

Necrotic tissue at the bronchial anastomosis is an ideal medium for the growth of saprophytic fungi. These infections can be a significant source of morbidity. In one study, saprophytic fungal infections involving the bronchial anastomosis occurred in 25% of recipients surviving a minimum of 75 days after transplantation. In 47% of those patients with fungal involvement of the anastomosis, airway complications occurred.⁹⁶

Anastomotic Stenosis

Chronic airway stenoses result from surgical stenosis, granulation tissue, infection, or bronchomalacia, with ischemia as the universal common denominator. Bronchoscopic balloon dilation may be attempted, and this may avoid the need for stent placement.¹¹⁸ We have used Silastic endobronchial stents to treat this problem.¹¹⁹ Daily inhalation of *N*-acetylcysteine is required to keep the stents patent. Most of these stents are only needed temporarily, because after several months, most patients are able to maintain satisfactory airway patency without a stent. When airways distal to an anastomotic stricture are too small to accept a Silastic stent, or when a Silastic stent will obstruct one bronchus while stenting another, a self-expanding metal stent may be used. However, granulation tissue rapidly overgrows a bare metal mesh stent, sometimes making it impossible to remove. Self-expandable silicone stents have also been used. Treatment of the granulation tissue consists of a combination of laser or forceps débridement, dilation, and stenting.¹¹² Recurrent airway stenoses have been managed with topical application of mitomycin C¹²⁰ and with high-dose brachytherapy.¹²¹ Finally, if bronchial strictures prove unmanageable by dilation or stent insertion, sleeve resection¹²² and retransplantation are available options.¹²³

Chronic Rejection: Bronchiolitis Obliterans Syndrome

Chronic rejection of the lung allograft is the major limitation to long-term recipient survival (Fig. 14-17). Within 5 years of transplantation, BOS develops in 49% of recipients, and in 76% of recipients by 10 years post-transplant.²⁰ In addition, 5 years after transplantation, BOS accounts for 20% of deaths.²⁰ The hallmark clinical feature of BOS is the development of airway obstruction with a reduction of FEV₁ that does not respond to

FIGURE 14-17 ■ Transbronchial lung biopsy showing bronchiolitis obliterans with scarring and fibrosis of the small airways (arrow; hematoxylin and eosin stain).

bronchodilators. The key histologic finding of chronic rejection is obliterative bronchiolitis, an inflammatory process that affects small noncartilagenous airways (see Fig. 14-17).¹²⁴ Bronchiolitis obliterans is a patchy heterogeneous process, thus transbronchial biopsy has a sensitivity of only 22% to 73% in the diagnosis of chronic rejection.¹²⁵ The clinical diagnosis of BOS requires a sustained decline in FEV₁ for more than 3 weeks and other causes of a decrease in lung function need to be excluded: acute rejection, anastomotic complications, and infection.¹²⁴ The diagnosis of BOS does not require the presence of histologically documented bronchiolitis obliterans.

The best posttransplant FEV₁ is determined and used as the baseline against which future measurements are compared. A decline from this baseline determines the stage of BOS. Patients cannot receive a diagnosis of BOS until at least 3 months after transplantation. The absence or presence of bronchiolitis obliterans is noted by subcategories “a” and “b,” respectively. Table 14-3 shows the current classification system.¹²⁶ The forced expiratory flow 25% to 75% (FEF₂₅₋₇₅) is part of the classification and has been shown to be more sensitive than FEV₁ for the detection of early airflow obstruction in bilateral-lung transplant recipients,¹²⁷ but it has wide variability with single-lung transplants. Airway neutrophilia detected on BAL,¹²⁷ elevated exhaled nitric oxide fraction,¹²⁸ and air trapping on an expiratory CT scan¹²⁹ are additional diagnostic tests that indicate BOS. A recent review reported the risk factors for development of BOS (Box 14-7).¹²⁴ Interestingly, gastroesophageal reflux disease is a potential risk factor for BOS. In lung transplant patients who undergo early fundoplication, both freedom from BOS and survival were improved when compared with patients with reflux and no fundoplication.¹³⁰

Therapeutic options for bronchiolitis obliterans are limited, and once present, it is generally irreversible. Standard treatment protocols consist of augmenting immunosuppression in an attempt to stabilize the disease process. Regimens such as high-dose corticosteroids,

TABLE 14-3 Criteria for Bronchiolitis Obliterans Syndrome*

BOS Score	Degree	Baseline FEV ₁ (%)
0	None	>90, and FEF ₂₅₋₇₅ >75%
0-p	Potential	81-90 and/or FEF ₂₅₋₇₅ ≤75%
1	Mild	66-80
2	Moderate	51-65
3	Severe	≤50

*Each bronchiolitis obliterans syndrome (BOS) score has a subcategory noting the histologically documented absence or presence of bronchiolitis obliterans: *a* indicates "without pathologic evidence of bronchiolitis obliterans," and *b* indicates "with pathologic evidence of bronchiolitis obliterans."

FEV₁, Forced expiratory volume in 1 second; FEF, forced expiratory flow.

BOX 14-7 Risk Factors for Bronchiolitis Obliterans Syndrome after Lung Transplantation

PROBABLE ROLE

- Acute rejection
- Cytomegalovirus (CMV) pneumonitis
- HLA mismatching
- Lymphocytic bronchitis/bronchiolitis
- Noncompliance with medications
- Primary graft dysfunction

POTENTIAL ROLE

- *Aspergillus* spp. colonization of lower airways
- Aspiration
- CMV infection (without pneumonitis)
- Donor antigen-specific activity
- Epstein-Barr virus reactivation
- Etiology of native lung disease
- Gastroesophageal reflux
- Older donor age
- Pneumonia (gram-negatives, gram-positives, fungi)
- Prolonged allograft ischemia
- Recurrent infection other than CMV

From Hayes D, Jr: A review of bronchiolitis obliterans syndrome and therapeutic strategies. *J Cardiothorac Surg* 6:92, 2011.

cytolytic therapy, substitution of MMF for azathioprine, and conversion of cyclosporine to tacrolimus have sometimes been successful at preserving pulmonary function.^{131,132} A single-center, randomized controlled trial of aerosolized cyclosporine given within 6 weeks of lung transplant along with routine systemic immunosuppression showed that, although the rate of acute rejection was unaffected, the patients receiving inhaled cyclosporine had improved survival and longer periods of chronic

rejection-free survival.¹³³ Several studies have demonstrated an improvement in FEV₁ with azithromycin therapy for 3 to 6 months.^{134,135} Statins (3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors) have immunomodulatory effects, and one report showed that acute rejection in lung transplant patients was less common in those taking statins.¹³⁶ In addition, none of the lung transplant patients taking statins developed BOS, but 37% of those not taking them did develop it, and the 6-year survival rate of patients taking statins was greater than those not (91% versus 54%, respectively).¹³⁶ Extracorporeal photopheresis therapy has also been shown to reduce the rate of decline in lung function, and 25% of patients in one study had an improvement in FEV₁.¹³⁷

Unfortunately, most patients either acquire progressive bronchiolitis obliterans or a lethal opportunistic infection as a result of the augmented immunosuppression. Retransplantation may be an option in carefully selected patients with BOS. BOS does not appear to occur in an accelerated manner after retransplantation. In the pulmonary retransplant registry, 81% and 56% were free of BOS at 1 and 4 years after retransplantation, respectively.¹³⁸ More recent studies indicate that the 1- and 5-year survival rates after retransplantation for BOS are similar to those for primary lung transplantation.¹³³

Posttransplant Lymphoproliferative Disorder

Posttransplant lymphoproliferative disorder (PTLD) is a well-recognized complication after solid-organ and bone marrow transplantation, with an incidence between 2% and 6% after lung transplantation (Fig. 14-18).^{139,140} It encompasses a spectrum of disease entities ranging from atypical lymphoid proliferation to malignant non-Hodgkin lymphoma.¹⁴¹ Most commonly, the cells are of B cell origin. There is an association between PTLD and Epstein-Barr virus (EBV).¹⁴² In lung transplant recipients, a strong correlation between negative EBV serology before transplantation and the development of PTLD has been reported. Studies have reported a 6.8- to 20-fold increased risk of development of PTLD in recipients who were EBV-negative before transplantation.¹⁴³

When it occurs in the first year after transplantation, PTLD shows a predilection for the thorax and commonly arises in the lung allograft.¹⁴⁰ In contrast, when patients present with PTLD after the first year, it is usually extrathoracic, commonly arising in the abdomen and pelvis (Fig. 14-19).¹⁴⁴ In our series, late-occurring abdominal and pelvic PTLD cases were most commonly malignant non-Hodgkin lymphomas, and, despite aggressive therapy, the prognosis was poor. In contrast, patients who had early-stage PTLD, unless disseminated disease was present at diagnosis, had a favorable prognosis and often responded to decreased immunosuppression.¹⁴⁴

The choice of treatment for PTLD is based on the stage and progression of disease. First, a trial of reduced immunosuppression is attempted, particularly with disease limited to the allograft. Others also have recommended the simultaneous use of antiviral therapy.¹⁴⁵ Although chemotherapy (cyclophosphamide, adriamycin,

FIGURE 14-18 ■ **A**, Computed tomographic scan of a patient with multiple pulmonary nodules that developed several months after bilateral lung transplantation. The patient was found to have posttransplantation lymphoproliferative disease (PTLD). **B**, Histopathologic examination of a posttransplantation lymphoproliferative nodule (hematoxylin and eosin stain). **C**, Immunostaining of a PTLN nodule found to be positive for Epstein-Barr virus (arrow).

vincristine, and prednisone [CHOP]) has been used in patients with widespread disease or with progression of disease, treatment-related mortality is considerable. Rituximab has been shown to be effective against CD20-positive B cell tumor cells and has been proposed as a first-line agent against PTLN. Several studies cite a response rate of approximately 66%.^{146,147} Preventive strategies for children may include matching recipient and donor EBV status, but this is not effective in adults because greater than 90% of the population are EBV-positive by the time they are 35 years old. One group reported that prophylactic use of antiviral therapy may reduce the incidence of PTLN.¹⁴⁸

FIGURE 14-19 ■ Computed tomographic scan from a patient with small bowel intussusception secondary to posttransplantation lymphoproliferative disease.

Gastrointestinal Complications

Gastrointestinal (GI) complications are common in lung transplant recipients, occurring in as many as 50% of patients in some series.¹⁴⁹ Nonsurgical GI complications, including esophagitis, gastroesophageal reflux, gastritis, gastric atony, peptic ulcer disease, pancreatitis, cholecystitis, CMV hepatitis, CMV colitis, GI bleeding, adynamic colonic ileus, diverticulitis, and *Clostridium difficile* colitis, or diarrhea, commonly occur in the first month postoperatively, and most patients respond to conservative therapy. Acute abdominal processes requiring an operation can occur at any point after transplantation and have an incidence of 4% to 17%. They include, in decreasing frequency, bowel perforation, appendicitis, cholecystitis, colitis, and pneumatosis intestinalis.¹⁵⁰ PTLN may appear as an acute abdominal process, secondary to intussusception (see Fig. 14-19) or bowel perforation. A high index of suspicion is needed to diagnose these GI complications, because immunosuppression can mask clinical signs and symptoms. Emergent operative exploration is associated with significant morbidity and mortality. Elective procedures, however, can be performed safely in this population with acceptable morbidity rates.¹⁵¹

RESULTS

Among survivors, functional results are excellent (Fig. 14-20). Patients usually return to normal levels of exercise tolerance without oxygen supplementation within 6 to 8 weeks after transplantation. Long-term results of more than 300 patients with emphysema who received transplants at Washington University from 1988 to 2000 have been reported,¹⁵² and updated data are available through 2012. The overall hospital mortality rate during the 13-year period (1988 to 2000) was 6.2%, but from 1995 to 2000, it was only 3.9%. All patients showed a significant improvement in posttransplantation functional outcomes measured by parameters such as FVC, FEV₁, and a 6-minute walk test. Since the

FIGURE 14-20 ■ Adult lung transplant recipient Kaplan-Meier survival by diagnosis, conditional on survival to 1 year (transplants: January 1990 to June 2011). A1ATD, α_1 -Antitrypsin deficiency–associated chronic obstructive pulmonary disease; CF, bronchiectasia associated with cystic fibrosis; COPD, non-A1ATD–associated COPD; ILD, interstitial lung disease, which includes idiopathic pulmonary fibrosis; IPAH, idiopathic pulmonary arterial hypertension. (From Yusef RD, Christie JD, Edwards LB, et al: The Registry of the International Society for Heart and Lung Transplantation: Thirtieth Adult Lung and Heart-Lung Transplant Report—2013; focus theme: age. *J Heart Lung Transplant* 32:965–978, 2013.)

implementation of the lung allocation score, IPF (29%) has become the most common indication for lung transplantation at our center, followed by chronic obstructive pulmonary disease (COPD) (25%) and cystic fibrosis (17%). From 1988 through 2012, 1216 primary transplants and 35 retransplants were done for a total of 1251 transplants; 1038 of these were bilateral-lung transplants and 194 were single-lung transplants. During this same time frame, 10-year survival rates were similar for all indications for lung transplantation, ranging from 31% to 43%. However, 15-year survival was highest for CF patients (32%), followed by IPF patients (25%), PPH/idiopathic pulmonary arterial hypertension (20%), α_1 -antitrypsin deficiency (17%), and COPD (16%).

Several centers have reported satisfactory results for patients with septic lung disease undergoing lung transplantation. The Toronto Lung Transplant Group reported excellent gas exchange, pulmonary function, and exercise ability among operative survivors.¹⁵³ The Washington University experience was similar, with overall survival comparable with that of patients with other indications for lung transplantation.

Fibrotic lung diseases such as IPF have been the indication for lung transplantation in more than one-third of all patients transplanted at our center since revision of the allocation system. The long-term survival is lower than that of patients with other diagnoses at early and later time points (see Fig. 14-20). Early mortality is probably affected by the complexity of transplants in fibrotic patients, whereas the late mortality may be affected by the older age of recipients relative to those transplanted for CF, PPH, or α_1 -antitrypsin deficiency.²⁰

From 1989 to 2001, our program performed 100 transplants for either PPH or secondary pulmonary hypertension, with 55 adult and 45 pediatric recipients of 51 bilateral-lung, 39 single-lung, and 10 combined heart-lung transplantations.¹⁵⁴ The overall hospital mortality

rate in this complicated group of patients was 17%, with a mortality rate of 10.4% among those transplanted for PPH and 23.1% among those transplanted for secondary pulmonary hypertension. The morbidity rate was also significantly higher compared with patients transplanted for emphysema: almost 25% of patients were taken back to the operating room for bleeding, 24% were reintubated, 17% needed a tracheostomy for prolonged ventilator support, and 16% required ECMO support. Among the surviving patients, there was a significant and sustained improvement in right ventricular function as well as pulmonary artery pressure and resistance.

PEDIATRIC LUNG TRANSPLANTATION

Lung transplantation was expanded to the pediatric population in a judicious manner in the late 1980s. The number of lung transplantations for recipients younger than 18 years of age was 107 for the year 2011, as reported by the ISHLT.¹⁵⁵ This number has remained stable over the past decade and represents a small proportion of the total lung transplantation procedures performed. The most common indications for lung transplantation in infants (<1 year) are congenital heart disease and surfactant protein B deficiency, each representing 16.7% of the transplants done in this age group between 1990 and 2012.¹⁵⁵ Of children between 1 and 5 years of age, 22.4% of lung transplantations were done for PPH and 16.8% for IPF. CF is the predominant indication for lung transplantation in children between 6 and 10 years of age (53%) and teenagers between 11 and 17 years of age (70.6%). With the revision of the lung allocation system, lungs are allocated to potential recipients younger than 12 years of age on the basis of wait time on the transplant list. Potential recipients aged 12 to 17 years are prioritized based on their lung allocation score.¹⁵⁶

Survival after pediatric lung transplantation is comparable with that reported in adults with a median survival of 4.9 years versus 5.4 years, respectively.¹⁵⁵ Bilateral-lung transplant recipients show an improved survival compared with single-lung transplant recipients, but this may be an effect of underlying disease and other recipient factors. The vast majority of pediatric lung transplants are bilateral. As in adults, early mortality after pediatric lung transplantation is secondary to infections and graft failure, and late mortality is attributed mostly to bronchiolitis obliterans, with greater than 50% developing bronchiolitis obliterans by 5 years.¹⁵⁵

Only 20 to 30 centers are currently performing pediatric lung transplants. Our center began its pediatric lung transplant program in July 1990. Since its inception, 410 lung transplants have been done. Almost half of the lung transplants were done in patients with CF (47%). The second and third most common indications for lung transplant were pulmonary hypertension (12%) and bronchiolitis obliterans (7%). The age of recipients ranges from less than 1 month to 25 years. From 1998 through 2002, actuarial survival at our center was 77% at 1 year, 62% at 3 years, and 55% at 5 years. The most common cause of early mortality was graft failure. Late mortality was most commonly secondary to bronchiolitis obliterans (57%), infection (21%), and posttransplant malignancies (18%).¹⁵⁷

SUMMARY

Lung transplantation is an effective therapeutic option for selected patients with end-stage pulmonary disease. The use of marginal donors, non-beating-heart donors, and ex vivo lung perfusion has been implemented in an attempt to increase the donor pool. Lung preservation and immunosuppression strategies continue to evolve. Extensive research efforts are underway to find methods to overcome chronic rejection and prolong survival in patients undergoing lung transplantation.

MANAGEMENT OF THE SCREEN-DETECTED NODULE

SUMMARY

Lung cancer is a global health burden and is among the most common and deadliest of all malignancies worldwide. In the United States, lung cancer accounts for more than 25% of all cancer deaths, exceeding deaths from breast, colon, and prostate cancers combined.¹ More than 80% of individuals with lung cancer die of the disease, primarily because a large proportion of patients with lung cancer present with locally advanced or metastatic disease. Intuitively, early detection of resectable and potentially curable disease could reduce the overall death rate from lung cancer. Historically, screening for lung cancer was not recommended by the majority of clinical societies and health care agencies in the United States. However, following the mortality benefit identified in the National Lung Screening Trial (NLST) in 2011,² most U.S. guidelines now recommend screening with low-dose computed tomography (LDCT) in at-risk populations.³⁻⁶ This shift in policy can be expected to increase significantly the number of patients found to have lung cancer, but also those found to have benign lung nodules. Much of the current debate has turned toward identifying the most appropriate “at-risk” populations for screening, ensuring appropriate management of screen detected nodules, and defining the optimum duration of CT screening. This chapter briefly discusses the history of and rationale for lung cancer screening and addresses optimization of screening protocols.

HISTORY OF LUNG CANCER SCREENING

Chest Radiograph Screening

Interest in screening high-risk patients for lung cancer was sparked when the association between cigarette smoking and lung cancer was first appreciated by Doll and Hill in the 1950s.⁷ The first mass screening project was conducted by Brett in London from 1960 to 1964.⁸ Although not a randomized trial, 55,034 men were assigned to undergo either chest radiography (CXR) every 6 months for three years (the screened group) or a single CXR at the beginning of the study, followed by a repeat CXR at the end of the 3-year period (the “unscreened” group). At the end of the 3-year period, more lung cancers were detected in the screened group compared to the unscreened group (132 vs. 96 cases). In addition, resectability was enhanced in the screened group. Despite these findings, lung cancer–specific mortality was not different between the two groups.

In the 1970s, the National Cancer Institute funded three randomized trials for lung cancer screening using both CXR and sputum cytology at Johns Hopkins, Memorial Sloan-Kettering Cancer Center, and the Mayo Clinic.⁹⁻¹¹ Again, more cancers were found in the

screened groups of patients, and resectability rates were significantly higher in the screened group. Nonetheless, again there was no statistically significant difference in the lung cancer–specific mortality between the screened and unscreened populations in any of the trials.

Early Computed Tomography Screening Studies

In the 1990s, increased resolution and data-acquisition speeds of modern computed tomographic (CT) scanners rekindled interest in screening for lung cancer. Initial findings from Henschke and colleagues of the Early Lung Cancer Action Project (ELCAP) showed that in a high-risk population, LDCT was superior to CXR in detection of lung nodules.¹² Notably, 2.7% of those enrolled in the CT screening program had lung cancer, the great majority of which were stage I.^{13,14} A subsequent report by the I-ELCAP group addressed overall curability estimated through 10-year survival rates of patients found to have stage I lung cancer by CT screening.¹⁵ The authors reported an estimated 88% 10-year survival rate, markedly higher than survival rates predicted by the current staging system or among those presenting as a result of symptoms. They inferred that because CT screening leads to early detection of lung cancer and because those lung cancers found as a result of CT screening are curable, that CT screening leads to a reduction in lung cancer mortality. Several other groups subsequently evaluated CT screening for lung cancer. A review by Black and colleagues¹⁶ published in 2007 identified 12 studies, including two randomized and 10 single-arm observational studies. Significant variability existed in the study populations and in the definition of a positive finding in each. The percentage of positive screenings ranged from 5.1% to 51%. From baseline screenings, 1.8% to 18% of positive findings led to a diagnosis of cancer. The majority of the tumors were stage I (53% to 100%), with a high resectability rate (>78%). Only one of the studies reported 5-year survival: 76% for patients with cancer detected at baseline screening and 65% for patients with cancer detected at annual repeat scanning.¹⁷

Screening for lung cancer with LDCT was not universally embraced, however. Bach and colleagues¹⁸ reported the findings from CT screening of 3246 high-risk patients from multiple institutions. The authors reported a threefold increase in individuals diagnosed with lung cancer and a tenfold increase in patients undergoing lung resection (compared to expected cases). They also found no evidence of a decline in the number of patients with advanced stages of disease or of deaths from lung cancer in the screened groups. The authors concluded that CT screening might not meaningfully reduce the risk of dying from lung cancer and suggested that CT screening is inherently prone to overdiagnosis, thus exposing patients to unnecessary surgery. The study generated controversy given that the follow-up was relatively short (3.9 years) and that at least one of the three studies did not require the exclusion of symptomatic individuals, possibly undermining the core concept of screening.

MODELING APPROACHES TO ESTIMATE MORTALITY BENEFIT

Given the inability of early randomized trials and prospective studies to prove a mortality benefit to screening, others have attempted to address the magnitude of lung cancer mortality reduction using modeling approaches. McMahon and colleagues from the Mayo Clinic used 1520 current or former smokers undergoing CT screening to model predicted cases of lung cancer and deaths, which were compared to a simulated unscreened control arm.¹⁹ The model ultimately simulated 500,000 cases per study arm based on five annual screening examinations, to generate precise estimates of mortality. At 6 years of follow-up, the screening arm had an estimated 37% relative increase in lung cancer detection compared with the simulated control arm and a 28% relative reduction in cumulative lung cancer–specific mortality. The model included many assumptions such as lung cancer incidence rates, adherence to the screening protocol, and treatment by established guidelines, yet the study made a compelling argument for a mortality benefit from CT screening.

Similarly, Foy and colleagues used a lung cancer mortality model developed within the Cancer Intervention and Surveillance Modeling Network (CISNET) to address the potential for mortality reduction by CT screening for lung cancer.²⁰ The comparison matched members of a CT screening trial (NY-ELCAP) with age, sex, and tobacco exposure-matched control patients from the Beta-Carotene and Retinol Efficacy Trial, with well-established lung cancer incidence rates. The simulation was repeated 5000 times to compare expected lung cancer mortality between the two groups. Although again subject to inherent assumptions made for the purposes of modeling, the study suggested a 45.6% relative reduction in lung cancer mortality in the group of patients screened with CT.

More recently, a modeling study was performed by the CISNET on behalf of the USPTF. Models were created using de-identified data from the NLST and the Prostate, Lung, Colorectal, and Ovarian Cancer Screening (PLCO) trial.²¹ The authors judged a strategy of screening patients aged 55–80, with at least 30 pack-years, and no more than 15 years since quitting as the optimal scenario balancing benefits and harms. In this scenario, the estimated reduction in lung cancer mortality is between 8.6% and 23.5%. All these studies, albeit models, suggested that LDCT screening protocols, logically followed by earlier treatment of lung cancer, do likely provide a mortality benefit.

The Gold Standard: The National Lung Screening Trial

Between 2002 and 2009, the NLST enrolled 53,456 patients between the ages of 55 and 74 years.² Patients had a history of smoking at least 30 pack-years and were either current smokers or former smokers who had quit within the past 15 years. The majority of patients were male (59%) and younger than 65 years (73%). The group compared low-dose CT screening (26,723) with CXR screening (27,733) using three annual screening rounds with 8

TABLE 15-1 Results of the National Lung Screening Trial (2011)

Study Characteristics	CT-Screened Arm	CXR-Screened Arm
Total no. of patients	26,722	26,732
Screening interval and follow-up	Three annual screens with eight years of follow-up	Three annual screens with eight years of follow-up
Rate of positive screening over 3 rounds	24.2%	6.9%
False positive rate	96.4%	94.5%
Lung cancers confirmed after positive test	649 (2.4%)	279 (1.0%)
Surgical procedures following positive screening test	713	239
Total lung cancers in group	1060	941
Total lung cancer deaths	354	442
Relative decreases in lung cancer mortality in CT screened group	20.3%	
Relative decrease in overall mortality in CT screened group	7%	

CT, Computed tomography; CXR, chest radiography.

years of follow-up (Table 15-1). In the CT screening arm, there were 354 deaths from lung cancer, compared with 442 in the CXR group, translating into a 20.3% reduction in lung cancer–related mortality. Additionally, there was a 7% reduction in overall mortality in the CT arm of the trial. This absolute mortality reduction was unprecedented in the history of lung cancer screening and was greeted with much enthusiasm by advocates of CT screening. The NLST secondary analyses will continue to provide data over the coming years. In addition, several European randomized trials (MILD, DANTE, ITALUNG, NELSON, DLCST, LUSI, and UKLS)^{22–28} have or are comparing lung cancer CT screening with no screening. It is expected that pooling the results of these trials and the NLST will further clarify the role for CT screening and better define screening protocols. It should be noted that both the DANTE²³ and DLCST²⁶ trials failed to show a decrease in lung cancer mortality in the CT-screened patients; however, they were likely underpowered. The largest trial among these, the NELSON²⁵ study, has not yet reported end results.

Important Statistical Concepts

The efficacy of screening in reducing cancer-specific mortality may be confounded by lead time, length, and overdiagnosis biases. Although the statistical arguments may be examined from many different vantage points and are sometimes difficult to interpret, they have been well described previously by Strauss.²⁹ We will highlight some of those important concepts here.

In all screening trials, one must distinguish lead time from lead time bias. The success of any screening program

depends on a lead time in diagnosis and treatment, which itself does not present a problem. Bias can arise when short-term survival rates are used to assess the value of screening in populations with and without lead time. Lead time bias should not affect resectability or more importantly, curability. In the subpopulations of patients with lung cancer in the older screening trials, there were an increased proportion of 5-year survivors in the screen-detected cases compared with those in the control arms in both the Mayo and Czech studies.^{9,30} The survival curves never converged, suggesting that screening increased the cure rate of patients with cancer. These mature data imply that lead time bias does not explain differences in survival between those groups. The I-ELCAP investigators' effort to estimate 10-year survival rates, rather than shorter-term rates, was also an attempt to avoid any possible lead time bias.¹⁵ The estimated cure rate occurs at the plateau phase of the survival curve, its asymptote, at which point the additional deaths that occur are from competing causes. Ongoing analysis of mature NLST data as well as data from other randomized trials will help further to clarify any potential effect of lead time bias.

Length-bias essentially refers to the tendency of screening to lead to the diagnosis of slower growing cancers more frequently in the baseline round, as these tumors potentially may have been present for a considerable amount of time prior to the screening study. For tumors detected only on repeat rounds of screening, this is far less of a concern. A review of the Mayo data, however, demonstrates that survival rates were only slightly better in the prevalence cases when compared to incidence cases (40% vs. 33%), those diagnosed at repeat screening.²⁹ In the I-ELCAP, no distinction was made in survival rates between the prevalence and incidence groups. In the CT screening arm of the NLST trial, 270 (48%) cancers were diagnosed on the incident CT, compared with 379 (62%) following repeat screening.² Survival differences between the two groups were not reported, but they will be important to evaluate in future reports.

Similar to the length bias argument, the overdiagnosis hypothesis is based on the idea that screen-detected cancers may be indolent and perhaps even clinically insignificant. The lung cancer detection rates were higher in the screened groups in both the Mayo and Czech studies. Despite this, mortality for the entire screened cohort in both studies was actually slightly higher. Similarly, in the CT-based study by Bach and colleagues,¹⁸ there was an increased rate of lung cancer detection, 144 cases versus 45 expected cases. Despite this increase in detection, there was no decrease in the expected lung cancer mortality rate. The possibility of overdiagnosis has been used to explain these findings, as well as the excellent projected 10-year survival in the I-ELCAP study. Several authorities suggest that many lung cancers detected by screening would not progress rapidly to the point of clinical detection and would therefore be unlikely to account for a meaningful share of deaths among screened individuals.

Perhaps the most challenging aspect of understanding the issue of “overdiagnosis” is defining the term itself. The phrase is often used synonymously with “pseudo-disease,” which implies that the disease would progress slowly and would not lead to death before that

caused from a competing illness. This definition allows for patients with lung cancer who die of competing (or accidental) causes to be considered as examples of overdiagnosis regardless of tumor stage. The concept of overdiagnosis was first proposed based on data from the Mayo Lung Project. In that study, there was an excess of early-stage lung cancers in the screened group, yet no difference in mortality. Therefore, it was concluded that those excess predominantly early stage cancers were overdiagnosed. However, when examined critically, they did not fit the profile of indolent cancers. They were on average 2 cm in diameter, not present on the baseline round, had a median growth rate of 101 days, and were nearly all invasive pathologically.⁹ Thus, in the screened arm, lung cancers were far more likely to be identified and they cannot be thought of as indolent. The similar disease-specific survival rate between the groups could be explained by the high rate of competing causes of death in the screened group, in which the number of cardiovascular deaths was nearly four times the rate of lung cancer deaths.

There are several other arguments against overdiagnosis. For example, studies reported by Sobue and colleagues³¹ and by Flehinger and colleagues³² have documented mortality rates in excess of 80% for untreated screen-detected lung cancers. The high mortality of screen-detected small tumors argues against their presumed indolent or nonfatal nature. In fact, it seems that even the smallest lung cancers are almost always deadly. An analysis by Henschke and colleagues of the Surveillance, Epidemiology and End Results (SEER) database revealed an 87% 8-year fatality rate for untreated 6-15-mm primary non-small cell lung cancer (NSCLC).³³ A more recent review of the California Cancer Center registry by Raz and colleagues³⁴ examined long-term survival in untreated stage I NSCLC. Five-year overall survival was only 6%, with a median survival of 9 months.

More evidence against overdiagnosis can be found from autopsy studies. McFarlane and colleagues³⁵ reported that the rate of "surprise" lung cancer at autopsy was less than 1% and that many of these patients had in fact died from those cancers. Another study found a slightly higher (3.3%) rate of lung cancer at autopsy, but deemed none of the cancers to have been clinically insignificant, as lung cancer was thought to be the direct cause of death in over half of the cases.³⁶ Further evidence against overdiagnosis can also be found in the I-ELCAP data. Henschke and colleagues reported that for the I-ELCAP screening trial, an expert panel of pulmonary pathologists confirmed that 95% of the patients with stage I cancer had invasive tumors that were morphologically indistinguishable from "garden variety" lung cancers.¹⁵ In addition, a subgroup of the I-ELCAP screen-detected cancers was analyzed for biomarkers using immunohistochemistry and fluorescence in situ hybridization.³⁷ The molecular alterations were found to be similar to those found in conventionally diagnosed cancers. Of note, all eight I-ELCAP patients with untreated stage I cancer died within 5 years of screening.

Recently, Patz and colleagues³⁸ cited overdiagnosis as a potential reason for the mortality benefit in the NLST study. They used modeling estimates to determine that the probability is 18.5% (95% confidence interval [CI],

5.4% to 30.6%) that any lung cancer detected by screening with LDCT was an overdiagnosis, in particular that when a bronchioloalveolar (*noninvasive* in new terminology) lung cancer was detected with LDCT there was a 78.9% (95% CI, 62.2% to 93.5%) chance of overdiagnosis. In the NLST, there were 110 bronchioloalveolar cell carcinomas in the CT-screened arm, 95 of which were screen detected. In the CXR arm, there were only 35 bronchioloalveolar cell carcinomas, of which 13 were screen detected.² Given the lack of longitudinal studies to date, it is impossible to determine whether these were overdiagnosed indolent cancers or whether they would have progressed. The authors concede that as their model was based on only three annual screens and an average of 7 years of follow-up, any estimate of overdiagnosis based on lifetime follow-up scenarios must be treated cautiously. Although the natural history of noninvasive lung carcinomas is not well understood, in general, the balance of both epidemiologic and pathologic evidence does not appear to make lung cancer a good candidate for high rates of overdiagnosis by screening.

OTHER APPROACHES TO SCREENING

As reviewed by Brower³⁹ and by Hensing and Salgia,⁴⁰ a number of molecular alterations have been identified in premalignant bronchial lesions and in early lung cancer. These molecular abnormalities may be potentially identified in the sputum or blood of high risk patients. Common approaches to molecular biomarkers include novel high-throughput technologies for analysis of DNA, RNA, protein, and autoantibody expression in biological samples. Whereas all of these blood- or sputum-based tests offer promise for lung cancer detection, none have been extensively evaluated or applied to large screening populations. Several obstacles exist to developing a sensitive and specific test for early lung cancer, most importantly the heterogeneity of the disease. As such, it remains to be seen whether these techniques will play a role in screening for lung cancer. Currently there are no adequate standards to evaluate samples, with resulting large disparities among quantitative and qualitative reports. The hope, however, is that one day it will be possible to develop accurate blood and sputum tests to facilitate the diagnosis of lung cancer. Such tests will likely be combined with CT screening protocols, either using the biomarker to select patients for screening or to further risk stratify patients found to have nodules on CT screening.

CURRENT RECOMMENDATIONS

The American Association for Thoracic Surgery (AATS) created an interdisciplinary task force to structure recommendations for lung cancer screening to extend the findings of the NLST to long-term clinical practice and to address issues related to screening.⁴ Six unanimous recommendations were presented and accepted at the AATS 2012 annual meeting (Box 15-1). The group recommends screening smokers and former smokers with at least a 30 pack-year history from the ages of 55 to 79 years. In

BOX 15-1 American Association for Thoracic Surgery Guidelines Task Force Recommendations Regarding Low-Dose Computed Tomography Screening for Lung Cancer

1. Annual lung cancer screening with LDCT for smokers and former smokers between 55 and 79 years old with 30 pack-year history of smoking
2. Annual LDCT until the age of 79 in long-term lung cancer survivors to detect second primary lung cancers
3. Annual lung cancer screening with LDCT for smokers and former smokers between 55 and 79 years old with 20 pack-year history of smoking and additional comorbidities that infer increased risk of lung cancer greater than 5% over the following 5 years
4. Multidisciplinary approach to lung cancer screening, evaluation, and treatment
5. Development of a web-based application for patient self-risk assessment
6. Continue AATS engagement with other specialties to develop and refine further guidelines

AATS, American Association for Thoracic Surgery; LDCT, low-dose computed tomography.

Modified from Jaklitsch MT, Jacobson FL, Austin JH, et al: *The American Association for Thoracic Surgery guidelines for lung cancer screening using low-dose computed tomography scans for lung cancer survivors and other high-risk groups*. *J Thorac Cardiovasc Surg* 144:33–38, 2012.

addition, the AATS recommended screening patients aged 50 to 54 years with a 20-pack history if additional risk factors are present. Recommendations also addressed the need for surveillance with annual LDCT in lung cancer survivors, the need for patient self-risk assessment, and the need for multidisciplinary evaluation. Importantly, the AATS made no recommendation to stop screening after the 3-year time point used in the NLST, citing lack of scientific evidence for cessation of screening. The AATS also proposed that long-term cancer survivors should have an annual LDCT until the age of 79 years to screen for second primary lung cancers.

The U.S. Preventive Services Task Force³ recommendations are similar to those of the AATS. They recommend annual screening for patients aged 55 to 80 years with a 30 pack-year smoking history, but suggest discontinuing screening when patients have not smoked for 15 years. The USPSTF also addressed implementation of screening programs, smoking cessation counseling, shared decision making, and standardization of follow-up of abnormal findings. The National Comprehensive Cancer Network (NCCN) has also recommended LDCT screening in selected patients at risk for lung cancer.⁴¹ *High risk* is defined as patients aged 55 to 74 years with at least a 30 pack-year smoking history without cessation greater than 15 years prior. They also recommended that patients aged 50 years or older undergo screening when they have at least a 20 pack-year smoking history and one additional risk factor. In addition to the AATS, USPSTF, and NCCN, several other groups, including the American College of Chest Physicians, the American Society of Clinical Oncology, the American Cancer Society, and the American Thoracic Society, have all recommended screening for lung cancer with LDCT scan based on the

results of the NLST. Regardless of the method used to screen patients for lung cancer, controversy over the value and best paradigm of screening will likely continue to exist, much as it does for other cancers, including breast and prostate cancer. In 2009, the United States Preventive Services Task Force (USPSTF) released new recommendations for breast cancer screening, which were quite different from their 2002 recommendations.⁴² The Task Force raised the recommended age to begin screening from 40 to 50 years and recommended stopping screening at age 74. These recommendations generated significant national controversy. The USPSTF's interpretation of the screening data was subsequently refuted by some investigators who continued to claim a benefit for screening in the 40- to 84-year age range.⁴³ Similarly, the value of screening for prostate cancer has also been called into question by the results of two disparate landmark studies.⁴⁴ The European Randomized Study of Screening for Prostate Cancer reported a statistically significant cancer-specific mortality reduction of 20% favoring prostate-specific antigen-based screening.⁴⁵ In contrast, the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial showed no mortality reduction.⁴⁶ Undoubtedly, different structures of competing clinical trials, heterogeneous unscreened populations, and evolving technological advances will also continue to make an absolute application of the data for lung cancer screening to clinical practice difficult.

Screening Regimen

Screening regimens currently vary by institution. There are two major published guidelines from the NCCN and from the I-ELCAP group suggesting algorithms for lung screening, but no consensus currently exists. The American College of Radiology (ACR) is expected to present a structured assessment, management, and categorization algorithm for LDCT screened detected nodules in late 2014 termed Lung-RADS (Table 15-2). This is comparable to the BI-RADS and LI-RADS lexicons used for screening mammography as well as CT and MR imaging for hepatocellular carcinoma, respectively. Widespread adoption is anticipated, allowing for uniformity among screening centers and the ability to compare results with the ACR National Data Registry (NRDR: <http://www.acr.org/Quality-Safety/eNews/Issue-05-March-2014/CT-Lung-Screening>).

Our current local screening regimen begins with a definition of what constitutes a positive or negative screening result. A nodule must first, before entering into a management algorithm, be assessed for signs of benignity which would exclude it from further assessment. A nodule containing calcification, unless eccentric, is most likely benign.⁴⁷ Therefore, if it is the only finding, it is considered a negative result. Noncalcified nodules or nodules containing eccentric calcifications are subsequently evaluated by size criteria. Another sign of benignity is a nodule which contains fatty attenuation. These nodules are likely to represent hamartomas. In addition, there is mounting evidence that perifissural nodules—solid nodules attached to a fissural surface which are lentiform or triangular in shape—are most

TABLE 15-2 Lung-RADS Version 1.0 Category Descriptors and Management Recommendations

Category	Descriptor	Management	Probability of Malignancy	Estimated Population Prevalence
1. Negative	No nodules/definitely benign nodules	Continue annual screening with LDCT in 12 months	<1%	90%
2. Benign appearance or behavior	Low likelihood of cancer due to size or lack of growth			
3. Probably benign	Low likelihood of becoming clinically active cancer	6-month LDCT	1-2%	5%
4A/4B. Suspicious	Additional diagnostic testing and/or tissue sampling recommended	4A. 3-month LDCT or PET/CT	5-15%	2%
		4B. PET/CT or tissue sampling	>15%	2%

CT, Computed tomography; LDCT, low-dose computed tomography; PET, positron emission tomography.

likely benign.⁴⁸ This group evaluated participants of the NELSON trial and classified nodules on the baseline examination into those that fit the periferous nodule criteria. None of these nodules turned out to be malignant after 5.5 years of follow-up. Once a nodule is identified that does not meet the benign criteria, its density is evaluated and separated into those that are purely subsolid (ground glass attenuation) or contain any solid component. If the initial test result is positive, as defined by a diagnostic algorithm (Fig. 15-1), then this algorithm is followed until cancer is confirmed or the suspicion level is lowered to allow the patient to return to annual screening. If the initial test is negative, the patient is referred to the next screening round (annual).

Current helical CT scanning allows for images of less than 1 mm in slice thickness to be obtained in a single breath hold. As most lung screening centers obtain and interpret images using these thinner slices, it has resulted in detection of smaller nodules. NLST used a 4-mm cutoff in their diagnostic algorithm to consider a baseline scan as positive. Concerns with a relatively high false-positive rate in that trial have led some investigators to suggest using a larger size cutoff for considering a nodule to warrant closer follow-up than the recommended annual screening. Henschke and colleagues⁴⁹ retrospectively analyzed their screening cohort of 21,136 participants in I-ELCAP and applied more restrictive thresholds for identifying a nodule as positive. They found that using alternative threshold values of 6, 7, 8, and 9 mm resulted in a positive study frequency of 10.2% (95% CI, 9.8% to 10.6%), 7.1% (CI, 6.7% to 7.4%), 5.1% (CI, 4.8% to 5.4%), and 4.0% (CI, 3.7% to 4.2%), respectively. Use of these alternative definitions would have reduced the workup by 36%, 56%, 68%, and 75%, respectively, thus leading investigators to suggest further study using these higher threshold values. We currently use a cutoff of 6 mm for solid and subsolid nodules.

MANAGEMENT OF THE SCREEN-DETECTED NODULE

No matter how the current debate on screening unfolds or how the technology evolves, thoracic surgeons will

continue to be asked to evaluate individuals with either screen-detected or incidentally discovered small pulmonary nodules. The management of these patients presents several challenges. It is important to understand the likelihood of malignancy in relationship to nodule size. The overwhelming majority of nodules found by screening or on incidental studies are not cancer. A large proportion of these nodules are less than 6 mm on the baseline round of screening and therefore do not actually constitute a positive result. Even for larger nodules, it is important to reassure patients that a positive CT scan does not mean that they have cancer.

Several factors can influence the probability of cancer in a pulmonary nodule. Of these factors, nodule size is the most critical. Early studies suggested that the rate of malignant disease was 1% in nodules less than or equal to 5 mm, 24% in those 6 to 10 mm, 33% in those 11 to 20 mm, and 80% for those greater than 20 mm.¹² In addition, change in size is also one of the most important factors to consider, as nodules that demonstrate growth are considered to be active. Time to follow-up CT scanning is in part dependent on the initial size of the nodule (as measurement of the growth in small nodules is more challenging) and on whether the nodules were initially detected on the baseline or repeat round. The time to follow-up is typically shorter on the repeat round, as cancers found on repeat screening are typically faster growing.

Several factors other than size play a role in the probability of malignancy. Patients with numerous small nodules (>6) are generally thought to be at low risk for malignancy and more likely to have inflammatory lung disease. The consistency of the nodule also affects the probability of cancer, with some investigators suggesting that part-solid nodules have a higher rate of malignancy (63%) than nonsolid nodules do (18%), whereas solid nodules have the lowest malignancy rate (7%).⁵⁰ Other factors to consider are patient age, smoking history, occupational history, personal and family history of cancers, and endemic rates of granulomatous disease.

Our general algorithm for radiographic follow-up is presented in Figure 15-1. For nodules less than 6 mm in diameter or for nonsolid nodules less than 10 mm found on baseline CT, we recommend a repeat CT scan in 1 year. For solid or part-solid nodules measuring 6 to

10 mm in diameter, we obtain a repeat CT scan in 3 months to assess for growth or resolution. For nodules found on annual repeat screening, those less than 3 mm in diameter should return to annual screening, while those larger than 3 mm and smaller than 6 mm should have CT follow-up within 6 months. For those larger than 6 mm, a course of antibiotics and repeat in 1 month is an additional option. Libby and colleagues¹⁵ suggested that an initial 7- to 10-day course of antibiotics resulted in partial or complete resolution of 29% of nodules on baseline screening and 74% of nodules on repeat screening. In all instances, nodule growth should prompt careful consideration of a biopsy or closer follow-up. Positron emission tomography (PET) scans may be an additional diagnostic option for screen detected nodules, particularly for patients with nodules larger than 1 cm in diameter. Veronesi and colleagues⁵¹ reported the sensitivity and specificity of PET for screen detected lung nodules to be 89% and 93%, respectively. Median nodule size was 14 mm for their cohort of patients. Even for nodules less than 10 mm, sensitivity and specificity were 83% and 100%.

Once the possibility of cancer exists, it is imperative to establish an accurate tissue diagnosis. When a nodule is deemed to be suspicious for malignancy—based on baseline characteristics, positive PET scan findings, or the demonstration of growth—we typically proceed to percutaneous transthoracic needle biopsy, typically by fine-needle aspiration (FNA), even for nodules smaller than 10 mm. FNA performed at high-volume centers can be extremely accurate, with a sensitivity of 82% to 99% and a diagnostic accuracy of up to 97%.⁵² FNA can result in four possible outcomes: malignant, specific benign, nonspecific benign, and nondiagnostic. For malignant and specific benign nodules, the treatment course is clear. Patients with nonspecific benign and nondiagnostic results require further workup. A review by Savage and colleagues⁵³ of 74 cases of FNA with either nonspecific benign or nondiagnostic findings demonstrated an eventual malignancy rate of almost 18%. Such nonspecific diagnoses can include atypical cells or inflammation. Furthermore, as described by Travis and colleagues,⁵⁴ the histologic heterogeneity of lung adenocarcinoma continues to be defined, leading to the recent refinement of the algorithm for adenocarcinoma diagnosis in small biopsies.

We will typically repeat CT scans at short intervals (within 3 months), with or without a course of antibiotics, and gradually increase the interval to the subsequent scan so that nodule stability can be ascertained. Volumetric analysis with serial CT scans can also be performed to assess nodule growth over time and to infer malignancy. Unfortunately, such techniques are not universally available and are costly, and their feasibility of use is still questioned with part-solid nodules and nodules adjacent to vessels. Further growth necessitates repeat FNA or

surgical biopsy, depending on clinical suspicion and surgical risk.

In institutions in which CT-guided FNA is not routinely performed, there should be a higher reliance on more invasive diagnostic techniques for suspicious nodules, such as bronchoscopic biopsy or surgical biopsy, either by open thoracotomy or video-assisted thoracoscopic surgery (VATS). Bronchoscopic biopsy is an option for establishing tissue diagnosis, although the yield for flexible bronchoscopy has historically been low, especially in small peripheral nodules. Newer techniques, including endobronchial ultrasound and electromagnetic navigational bronchoscopy, have been reported to increase the diagnostic yield of transbronchial biopsy to upwards of 60%, even for small, peripheral lesions.^{55,56}

When surgical biopsy is necessary, VATS is thought to decrease postoperative morbidity when compared with open thoracotomy, but comes with the occasional difficulty of palpating and visualizing small lesions that are often found on screening studies. Several techniques are available to localize and excise small pulmonary nodules using a minimally invasive approach.⁵⁷⁻⁶² Preoperative marking with methylene blue, wire hooks, and metallic coils has been described. Reported complications are rare, but include marker dislodgement, pneumothorax, intrapulmonary hemorrhage, and air embolism. Sortini and colleagues⁶³ and other investigators have also reported good results with ultrasound localization, although this method is strongly operator dependent. Other groups have described a VATS radiotracer localization technique, with a success rate of 92% for nodules with a median size of 8 mm.⁶⁴ The technique can be applied to all pleural surfaces including interlobar regions with complete fissures and enables rapid and predictable intraoperative localization. The procedure uses readily available technical components with minimal additional cost. Regardless of the method used to localize small nodules, VATS resection typically can be performed with low morbidity, short hospital stays, and excellent diagnostic accuracy.

SUMMARY

Lung cancer continues to be a deadly disease. The goal of screening programs is to detect tumors in earlier, curable stages, consequently reducing disease-specific mortality. The issue of screening has great relevance to thoracic surgeons, who should play a leading role in the debate over screening and its consequences. This is especially important as screening protocols may generate a tenfold increase in the number of patients presenting for surgical resection.¹⁸ The burden is on thoracic surgeons to work in a multidisciplinary setting to guide and treat these patients safely and responsibly, with low morbidity and mortality rates of potential diagnostic or therapeutic interventions.

For part-solid nodules, recommendations are based on the mean diameter of the largest solid portion.

METASTATIC WORKUP

SUMMARY

In 2010, the most recent year for which numbers are available, there were 201,144 new cases of lung cancer (107,164 men and 93,984 women) in the United States.¹ With 158,248 deaths, lung cancer remains the leading cause of cancer-related deaths in both men and women. Of newly diagnosed cases, approximately 80% will be non-small cell lung cancer (NSCLC), and of these, 80% will involve metastatic or locally advanced disease. Only 20% will be in potentially surgically curable patients with early-stage disease, where complete resection yields 5-year survivals of 40% to 75%.²

Careful staging of newly diagnosed lung cancer is critical for several reasons. First, determining the patient's clinical TNM (tumor, nodes, metastasis) stage allows appropriate therapeutic decisions to be made on the basis of the specific stage of disease. This is particularly important for locally advanced disease in which multimodality therapy (induction or adjuvant) is standard care, as well as for metastatic disease when surgery should be avoided. Second, accurate staging allows the clinician to give the patient valuable prognostic information. Third, staging allows evaluation of new therapeutic interventions, and comparison of results of treatments between studies and institutions.

There are controversies about the extent of workup, and the methods used for staging have evolved during the past decade.

THE STAGING SYSTEM

Staging is a process through which the extent of lung cancer in a patient is determined by a combination of techniques including history, physical examination, imaging studies, and invasive procedures where appropriate. Before initiation of treatment, a clinical stage (cTNM) is generated. If surgical resection occurs, the operative findings and pathologic features determine the final pathologic stage (pTNM).

In 1974, the American Joint Committee for Cancer (AJCC) Staging developed a lung cancer staging system based on TNM descriptors.³ Naruke and coauthors⁴ devised the original lymph node map that placed nodes into stations on the basis of defined anatomic boundaries. This was subsequently modified for North America by the American Thoracic Society⁵ and by Mountain and Dresler.⁶ In 1986, the AJCC, International Union Against Cancer (UICC), and representatives from Japan proposed an International Staging System (ISS) for lung cancer that grouped patients with similar survival outcomes using anatomic criteria.⁷ This system was derived from analyses of a 3000-patient database at the M. D. Anderson Cancer Center (MDACC). The accuracy of the ISS was further confirmed by studies from Naruke⁸ and Watanabe.⁹ In 1997, analyses of the updated MDACC database of 5319 patients¹⁰ led to revision of the ISS,

FIGURE 16-1 ■ Regional lymph node stations for the staging of non-small cell lung cancer. Ao, Aorta; PA, pulmonary artery. (From Rusch VW, Asamura H, Watanabe H, et al: The IASLC lung cancer staging project: a proposal for a new international lymph node map in the forthcoming seventh edition of the TNM classification for lung cancer. *J Thorac Oncol* 4:568–577, 2009.)

incorporated into the sixth edition of the AJCC and UICC staging manuals.

In 1996, the International Association for the Study of Lung Cancer (IASLC) initiated an international staging project to form the basis of the seventh edition of the TNM staging system.¹¹ The goals of the project were to validate the individual T, N, and M descriptors using a larger database made up of medical and surgical patients from a wide geographic distribution.¹² Data on 100,869 patients, including 67,725 cases of NSCLC, were submitted to the database, and several changes were proposed.¹³ The existing N descriptors were validated and

not changed (Fig. 16-1).¹⁴ For the T descriptors, size cutoffs were added to the T1 and T2 tumors, and tumors greater than 7 cm in greatest dimension were designated as T3, in light of the prognostic significance of increasing size of the primary tumor (Table 16-1).¹⁵ Additional tumor nodules in the same lobe as the primary, previously known as “satellite nodules,” were reclassified from T4 to T3, and additional nodules in the ipsilateral lung became T4. The M descriptor was divided into M1a (for pleural metastases, malignant effusion, or contralateral pulmonary disease) and M1b (for extrathoracic metastases).¹⁶ After incorporating the suggested changes into

TABLE 16-1 Definitions for T, N, and M Descriptors in the Seventh Edition of the AJCC and UICC Staging Manuals**T (Primary Tumor)**

TX	Primary tumor cannot be assessed, or tumor is proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor ≤ 3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)*
T1a	Tumor ≤ 2 cm in greatest dimension
T1b	Tumor > 2 cm but ≤ 3 cm in greatest dimension
T2	Tumor > 3 cm but ≤ 7 cm or tumor with any of the following features (T2 tumors with these features are classified T2a if ≤ 5 cm) Involves main bronchus, ≤ 2 cm distal to the carina Invades visceral pleura (PL1 or PL2) Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor > 3 cm but ≤ 5 cm in greatest dimension
T2b	Tumor > 5 cm but ≤ 7 cm in greatest dimension
T3	Tumor > 7 cm or one that directly invades any of the following: parietal pleural (PL3) chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in the main bronchus (<2 cm distal to the carina*) but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina, separate tumor nodule(s) in a different ipsilateral lobe

N (Regional Lymph Nodes)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)

M (Distant Metastasis)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural (or pericardial) effusion†
M1b	Distant metastasis

*The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximally to the main bronchus, is also classified as T1a.

†Most pleural (and pericardial) effusions with lung cancer are due to tumor. In a few patients, however, multiple cytopathologic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and is not an exudate. Where these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient should be classified as M0.

AJCC, American Joint Committee for Cancer; UICC, International Union Against Cancer.

From Goldstraw P, Crowley J, Chansky K, et al: *The IASLC lung cancer staging project: proposals for the revision of the TNM stage groupings in the forthcoming (seventh) edition of the TNM classification of malignant tumours*. *J Thorac Oncol* 2(8):709, 2007.

TNM subsets, new stage groupings were identified that yield even distributions of overall survival among stages, particularly between stages IIA and IIB (Table 16-2).^{17,18}

DIAGNOSIS AND STAGING

Diagnosis and clinical staging begin with the initial history and physical examination. A single study may serve the dual purpose of securing a diagnosis and staging the patient. If a patient's treatment is nonsurgical or involves multimodality therapy, obtaining a tissue diagnosis prior to treatment is mandatory. If it appears that the patient's clinical stage will be most appropriately managed by surgical resection alone, tissue confirmation of malignancy can be secured either preoperatively or at

the time of exploration, depending on the preference of the operating surgeon.

History and Physical Examination

Patients often come to the surgeon for evaluation with some studies already performed. However, the history and physical examination remain important in the initial evaluation. A detailed history focusing on risk factors—such as duration of cigarette smoking, exposure to asbestos and other industrial hazards, a prior history of lung cancer, and the presence of symptoms—allows the clinician to assess the likelihood of a diagnosis of lung cancer. Bach and associates showed that the duration of tobacco smoking, more so than the amount of daily usage, increases an individual's risk of developing lung cancer.¹⁹

TABLE 16-2 Descriptors, Proposed T and M Categories, and Proposed Stage Groupings*

Sixth Edition T/M Descriptor	Seventh Edition T/M	N0	N1	N2	N3
T1 (≤2 cm)	T1a	IA	IIA	IIIA	IIIB
T1 (>2-3 cm)	T1b	IA	IIA	IIIA	IIIB
T2 (≤5 cm)	T2a	IB	IIA	IIIA	IIIB
T2 (>5-7 cm)	T2b	IIA	IIIB	IIIA	IIIB
T2 (>7 cm)	T3	IIIB	IIIA	IIIA	IIIB
T3 invasion		IIIB	IIIA	IIIA	IIIB
T4 (same lobe nodules)		IIIB	IIIA	IIIA	IIIB
T4 (extension)	T4	IIIA	IIIA	IIIB	IIIB
M1 (ipsilateral lung)		IIIA	IIIA	IIIB	IIIB
T4 (pleural effusion)	M1a	IV	IV	IV	IV
M1 (contralateral lung)		IV	IV	IV	IV
M1 (distant)	M1b	IV	IV	IV	IV

*These revisions were incorporated into the seventh edition of the AJCC and UICC staging manuals.

From Goldstraw P, Crowley J, Chansky K, et al: The IASLC lung cancer staging project: proposals for the revision of the TNM stage groupings in the forthcoming (seventh) edition of the TNM classification of malignant tumours. *J Thorac Oncol* 2(8):709, 2007.

The lung cancer risk associated with asbestos exposure also increases with the intensity and length of exposure, and together, tobacco use and asbestos exposure have a multiplicative effect. Symptoms, such as bone pain, hoarseness, weight loss, and neurologic changes, can indicate the presence of metastatic disease and direct further investigation.

A physical examination is also important. It provides an estimate of a patient's overall health status, which influences treatment selection. Physical findings, such as Horner syndrome, or the presence of clubbing, may support the suspicion of lung cancer. Physical examination may also demonstrate advanced disease. For example, palpation of the supraclavicular fossae can reveal lymph node metastases, and auscultation of the lung fields can identify the presence of a malignant pleural effusion.

NONINVASIVE MODALITIES

Chest Radiography

Posteroanterior and lateral chest radiographs, often done for unrelated reasons, are a common initial study in which a suspected lung cancer is identified. However, most lesions are not visible until they are at least 7 to 10 mm in diameter.²⁰ A chest radiograph can localize the site of suspect lesions (central or peripheral) and the associated effects of disease, such as atelectasis, consolidation, or proximity to the pleural surface. The presence of a pleural effusion of chest wall invasion or of phrenic nerve involvement causing elevation of the hemidiaphragm may also be seen. Advanced disease may be identified in the case of rib destruction from bone metastases or synchronous lesions in the pulmonary parenchyma. Hilar and mediastinal lymph node metastasis is more

difficult to identify, unless there is substantial enlargement.

Sputum Cytology

Cytologic analysis of sputum for malignant cells is a simple diagnostic technique but is rarely used in North America because of the epidemiologic shift from centrally located squamous cell to more peripherally located adenocarcinomas. However, sputum cytology is still a potentially relevant test in other parts of the world where squamous cell cancers are more common. Samples may be induced by saline nebulization or collected as a 3-day pool of sputum produced from spontaneous coughing in the morning. Based on 16 published studies of at least 50 patients each, the overall sensitivity is 66% (range, 42% to 97%) and the overall specificity is 99% (range, 68% to 100%). When sputum cytology is used for patients suspected of having lung cancer on clinical grounds, the diagnostic yield is higher, with a sensitivity of 87% and a specificity of 90%.²¹

Low-Dose Computed Tomography

An increasing number of patients, particularly in developed countries, now have lung cancers identified by low-dose computed tomography (CT) because of the results of a large prospective U.S. randomized clinical trial. The National Lung Screening Trial (NLST) enrolled 53,454 persons at high risk (participants between ages 55 and 74 years with at least 30 pack years of smoking) for lung cancer at 33 medical centers and randomized them to undergo three annual screenings with either low-dose CT or posteroanterior chest radiography. Patients in the low-dose CT group had a significantly lower risk of death from lung cancer (20% relative risk reduction) and from any cause. The majority (63%) of lung cancers detected by low-dose CT were stage I tumors.^{22,23} The use of low-dose CT will likely increase in the future, largely supplanting chest radiography.

High-Resolution Computed Tomography

Once a suspect lesion has been detected on a chest radiograph or a low-dose CT, the next step is a high-resolution CT of the chest and upper abdomen, preferably performed with intravenous contrast. This yields information about the size, characteristics (e.g., spiculation, ground-glass opacification, lack of calcification), and local extent of a potential lung cancer. Potential invasion of contiguous chest wall or mediastinal structures can be assessed.

CT also provides details about the remaining lung parenchyma and pleural spaces. "Satellite" or additional nodules, bullous or emphysematous changes, pleural thickening, masses, or effusion may be identified. The chest CT for a suspected lung cancer should include the upper abdomen, through the liver and adrenal glands. Although most asymptomatic incidental lesions in the upper abdomen are benign (adrenal adenoma, hepatic cysts), unsuspected metastases are identified in a small percentage of patients.

Chest CT also allows assessment of mediastinal lymph nodes. The use of intravenous contrast is important in distinguishing nodes from vascular structures. The most widely used criterion to define abnormal lymph nodes is a short-axis diameter of 1 cm or greater. Although CT is the most accurate radiographic method of measuring lymph node enlargement, it does not reliably predict metastatic disease. Toloza and colleagues²⁴ reported results of a meta-analysis of 20 studies with 3438 evaluable patients that showed an overall sensitivity of 57% and specificity of 82%. Therefore, staging of the mediastinum and subsequent therapeutic decisions should not be based solely on the results of the CT.

Positron Emission Tomography

Whole-body positron emission tomography (PET) is a physiologic imaging technique based on the detection of positrons emitted by low-atomic-weight isotopes (carbon, fluorine, oxygen, nitrogen). Fluorodeoxyglucose (FDG) labeled with radioactive fluoride (¹⁸F) is a D-glucose analog that is phosphorylated after cellular uptake and accumulates intracellularly, rather than being metabolized. Because lung cancer cells have an increased rate of glycolysis and overexpress the glucose transporter, there is preferential accumulation and visualization of FDG in the primary tumor and in potentially metastatic sites (Fig. 16-2).²⁵ The criterion for an abnormal PET scan is either a standardized uptake value (SUV) of greater than 2.5 or uptake in the lesion that is greater than the background activity of the mediastinum. The lower limit of resolution of PET is approximately 1.0 to 1.2 cm and thus PET may not detect very small malignant lesions. Benign inflammatory or infectious conditions (e.g., granulomas, sarcoidosis) can also produce false-positive PET findings.

Despite these limitations, PET has become an invaluable tool in lung cancer staging.

Several studies have shown that PET is superior to CT in staging the mediastinum in lung cancer patients. Pieterman and colleagues²⁶ prospectively compared standard staging approaches to PET for detection of mediastinal lymph node and distant metastases in 102 patients with resectable NSCLC who underwent histologic staging of the mediastinum. The sensitivity and specificity of PET for detection of mediastinal nodal metastases were 91% and 86%, respectively, compared with a sensitivity of 75% and a specificity of 66% for CT. A meta-analysis of 18 studies demonstrated an overall sensitivity of 84% and specificity of 89%.^{24,26} Toloza and associates²⁴ also showed that combining CT and PET resulted in the highest diagnostic accuracy, with a sensitivity of 94% and a specificity of 86%, supporting the use of both modalities for staging of the mediastinum. PET also resulted in a stage different from the one arrived at by the standard methods in 62 of 102 patients, correctly indicating a lower stage in 20 patients and a higher stage of disease in 42 patients. PET was effective in identifying occult metastatic disease. In 11 patients (11%), PET demonstrated distant metastatic disease in bone, liver, and adrenal glands not detected by CT.

During the past decade, integrated PET-CT scanners have replaced PET alone, leading to improved diagnostic accuracy and anatomic localization of disease.²⁷ Cerfolio and coauthors compared PET with and without integrated CT in 129 patients with biopsy-proved or suspected NSCLC who subsequently underwent surgical staging.²⁸ PET-CT was a significantly better predictor of stages I and II disease and demonstrated superior accuracy for both T status (70% versus 47%, $P = 0.001$) and N status (78% versus 56%, $P = 0.008$) compared with

FIGURE 16-2 ■ Positron emission tomography–computed tomography (PET-CT) showing a right superior sulcus tumor (A) and the presence of an asymptomatic retroperitoneal metastasis (B).

PET alone. Moreover, PET-CT was more sensitive and more specific and had a higher positive predictive value for the status of N1 and N2 disease ($P < 0.05$). As in prior studies, PET-CT identified 19 (14.7%) patients with M1 disease.

PET-CT has proved to be more accurate than a bone scan, with a similar sensitivity and a higher specificity.²⁹⁻³² In the largest study comparing PET with bone scan, Song and colleagues retrospectively analyzed 1000 newly diagnosed patients, 105 of whom were eventually diagnosed with bone metastases and underwent PET-CT and bone scan.³¹ PET-CT was more accurate (98.3% versus 95.1%, $P < 0.001$), sensitive (94.3% versus 78.1%, $P = 0.001$), and specific (98.8% versus 97.4%, $P = 0.006$) than bone scan. PET-CT also showed a lower incidence of false positives (1.2% versus 2.9%) and false-negative results (5.7% versus 21.9%) compared with a bone scan. Agreement between PET-CT and bone scan findings was good, with a calculated $\kappa = 0.732$. Based on its clear advantages in both intra- and extrathoracic staging, PET-CT is now a routine part of pretreatment staging.

Bone Scan

Although PET-CT has essentially replaced bone scans for evaluation of potential skeletal metastases, when used in the setting of a positive clinical assessment (e.g., bone pain or tenderness), a technetium-99m methylene diphosphate (99mTc MDP) whole-body bone scan is relatively sensitive but not specific. In their meta-analysis of seven studies and 633 patients, Toloza and colleagues²⁴ showed that bone scans have an overall sensitivity of 87% and specificity of 67%. False-positive abnormalities are more common when scans are done in asymptomatic patients and can be the result of degenerative or traumatic skeletal injury. Follow-up with magnetic resonance imaging may or may not aid in establishing a definitive diagnosis. False-negative results, although uncommon, do occur, and in one series 6% of patients with an initially negative bone scan developed confirmed skeletal metastases within 1 year.³³

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the chest offers few advantages over CT in the diagnosis or staging of lung cancer. Heelan and coworkers³⁴ evaluated both CT and MRI in otherwise operable patients with NSCLC and found that MRI was no more accurate than CT in identifying hilar or mediastinal lymph node metastases and actually had a higher false-positive rate. In a recent study, whole-body MRI with diffusion-weighted imaging was compared with FDG-PET-CT in 33 patients before surgery for lung cancer. Whole-body MRI had comparable sensitivity, specificity, and accuracy for tumor detection and staging but showed no superiority to PET-CT.³⁵ However, MRI can be useful in some situations. When tumors are adjacent to the spine, MRI provides superior visualization of the spinal canal and can more accurately detect subtle changes in the marrow suggestive of invasion. It also delineates the relationship of a superior

sulcus carcinoma (Pancoast tumor) to the subclavian vessels and brachial plexus more accurately than CT.

INVASIVE MODALITIES

Bronchoscopy

Rigid or flexible bronchoscopy with conventional white light allows visualization of the tracheobronchial tree and is a standard part of evaluating patients with known or suspected lung cancer. It serves several critical purposes: diagnosis, staging, assessment of resectability, and visualization of the remaining bronchial tree. Flexible video-assisted bronchoscopy has replaced rigid bronchoscopy for all but a few special circumstances. It is generally performed as an outpatient procedure on a spontaneously breathing patient through the nasal or oral route, following topical anesthesia and sedation. The tracheobronchial tree up to the second or third subsegmental bronchi is easily visualized. The options available to secure a diagnosis include direct biopsy, brushing, saline lavage for cytology, and transbronchial needle aspiration (TBNA) with or without fluoroscopic guidance. Using more than one technique (e.g., biopsy, brushing, and cytologic lavage) generally improves the diagnostic yield.

When bronchoscopy reveals an endobronchial tumor, biopsy is best accomplished with either a forceps or brush biopsy, with sensitivities in the range of 80% to 100%.^{36,37} Positive endobronchial findings are common in cases of squamous and small cell cancers because of their central location. In contrast, a bronchoscopic examination is likely to yield normal findings when there are peripheral lesions, and the diagnostic sensitivity of bronchoscopy varies widely from 37% to 98%, depending on the size and location of the target lesion. Increasing size and presence of a bronchus sign (a bronchus leading to or contained in a lesion on CT) portend a higher diagnostic yield.³⁷ The use of fluoroscopy to guide a transbronchial biopsy or TBNA and lavage can improve diagnostic accuracy up to 80%.³⁸ Electromagnetic navigation bronchoscopy (ENB) is a new technology that uses high-resolution CT to guide transbronchial biopsy in real time during bronchoscopy. The CT-based "navigation" of the bronchoscope allows accurate biopsy of small peripheral lung lesions, especially when coupled with rapid on-site cytologic evaluation.³⁹

TBNA can also be used when there is bronchial distortion (thickening or blunting of the carina, extrinsic compression) secondary to the lesion or metastatic lymph nodes. Popularized by Wang and Terry, TBNA is performed with a 20- to 22-gauge, rigid needle through the channel of the fiberoptic bronchoscope to puncture the airway in the area of interest.⁴⁰ It is a safe and inexpensive procedure with an overall sensitivity of 50% and a specificity of 96%.^{36,37} As previously mentioned, diagnostic yield is enhanced by the use of fluoroscopy, as well as the use of rapid, on-site cytopathology. A positive result, especially from a mediastinal lymph node station, can obviate further surgical staging, although a negative result should still be confirmed surgically. Limitations include a sensitivity of only 30% for small (<2 cm),

peripheral lesions and inaccessibility of certain lymph node stations, including anterior, aortopulmonary, paraesophageal, and pulmonary ligament nodes. This technique has now been largely supplanted by the more recent development of endobronchial ultrasound.

Endobronchial Ultrasound

In an effort to improve on the diagnostic accuracy of TBNA, endobronchial ultrasound (EBUS) was developed and commercially introduced in the early 1990s.⁴¹ The original probe was radial, and radial EBUS guidance was shown to improve the yield of TBNA in the lymph node staging of lung cancer.^{42,43} Subsequently, an ultrasonic endoscope with a built-in linear-array, convex probe at the tip was developed by the Olympus Corporation (Tokyo) to enable real-time EBUS-guided TBNA. This EBUS is integrated with a convex transducer at 7.5 MHz at the tip of a flexible bronchoscope (XBF-UC260F-OL8, Olympus), whose angle of view is 90 degrees and direction of view is 30 degrees forward oblique. The ultrasound scans parallel to the insertion direction of the scope, and images are obtained by directly contacting the probe, with or without a saline-filled balloon at the tip. The ultrasound image is processed by a dedicated scanner (EU-C2000) that allows for image freezing, size measurement, and Doppler mode. A special 22-gauge needle is passed under direct visualization through the instrument channel to biopsy the target lesion through the bronchial wall (Fig. 16-3). The procedure can be done under monitored anesthesia care or general anesthesia. Indications for EBUS-TBNA include diagnosis of lung and mediastinal tumors and assessment of mediastinal and hilar lymph nodes. Accessible nodal stations include levels 2, 3, 4, 7, 10, and 11. Subaortic, paraesophageal, peribronchial, segmental, and subsegmental nodes are generally not approachable.

Several studies have shown the accuracy of EBUS-TBNA for mediastinal and hilar nodal staging in NSCLC.⁴⁴⁻⁴⁶ In one of the earliest series, Yasufuku and colleagues⁴⁵ successfully performed EBUS-TBNA in 105 patients with proved or suspected lung cancer and adenopathy by CT criteria alone. They sampled 163 lymph

nodes and reported an overall diagnostic accuracy rate of 96.3%, with a sensitivity of 94.6% and a specificity of 100%. Of note, patients who proved to have benign disease were excluded from analysis, and not all patients had confirmatory surgical biopsy of the nodal stations biopsied by EBUS. In a subsequent prospective controlled trial, Yasufuku and colleagues performed EBUS-TBNA followed immediately by cervical mediastinoscopy, in 153 patients with known or suspected lung cancer. No significant differences were found between EBUS-TBNA and mediastinoscopy with respect to sensitivity, negative predictive value, diagnostic accuracy, and determination of true pathologic N stage.⁴⁷ The same group of investigators has also reported that EBUS-TBNA can accurately access hilar and interlobar lymph nodes.⁴⁸ The accuracy of EBUS-TBNA is enhanced by rapid on-site evaluation (ROSE) of cytology specimens during the procedure, which also optimizes specimen submission for tumor molecular profiling.⁴⁹ A recent meta-analysis of 1066 patients from nine studies confirms the excellent accuracy of EBUS-TBNA.⁵⁰ In many centers, EBUS-TBNA has largely replaced mediastinoscopy in the staging of resectable NSCLC.

Autofluorescence Bronchoscopy

Detection and treatment of dysplastic or early invasive centrally located neoplastic lesions whose presence is suggested by positive sputum cytology remain a challenge. Approximately one third of patients with positive sputum cytology, but radiographically occult lung cancers, require more than one bronchoscopy for localization.⁵¹ In an effort to improve identification of superficial bronchial mucosal malignancy, Hung and associates⁵² were able to demonstrate that normal and malignant bronchial mucosa have different autofluorescence intensities under blue light (wavelength, 442 nm). This led to the development of the LIFE (light imaging fluorescence endoscope) Lung system (Xillix Technologies, Richmond, BC, Canada). Whereas normal bronchial mucosa appears green, premalignant and malignant tissue appears brown-red.⁵³ Subsequent prospective trials comparing white-light bronchoscopy alone with white-light bronchoscopy

FIGURE 16-3 ■ **A**, CT scan of the chest revealing enlarged right paratracheal lymph node. **B**, Endobronchial ultrasound (EBUS)-guided transbronchial needle aspirate of an enlarged right paratracheal lymph node.

plus LIFE have shown enhanced sensitivity in detection of intraepithelial neoplasms and invasive carcinoma.⁵³⁻⁵⁶ Lam and coauthors⁵⁶ reported the results of a multicenter North American trial of 173 patients that showed the relative sensitivity of white-light bronchoscopy plus LIFE versus white-light bronchoscopy alone to be 6.3 for intraepithelial lesions and 2.71 if invasive cancers were included. The role of LIFE was in preoperative screening for synchronous squamous carcinomas but in follow-up for recurrence or second primary tumors, and for monitoring intraepithelial dysplasia in some chemoprevention trials, it is not currently in widespread use. This relates in part to the epidemiologic shift away from centrally located squamous cancers and in part to the lack of development of more advanced autofluorescence technology than can be used outside of the research setting.

Percutaneous Transthoracic Needle Biopsy

Percutaneous transthoracic needle biopsy is a well-established procedure used to obtain a tissue diagnosis of lung cancer in patients who are not surgical candidates because of advanced disease or medical contraindications. However, with the identification of increasing numbers of noncalcified peripherally located pulmonary nodules by low-dose CT, transthoracic needle biopsy has become a critical tool in the detection of early-stage lung cancer. The accuracy of percutaneous needle biopsies has been enhanced by the development of fluoroscopy CT, which allows precise targeting of very small peripheral nodules for biopsy.^{57,58} The most common complications of the procedure are pneumothorax and mild hemoptysis. Although the reported incidence of pneumothorax varies greatly, the rate of postprocedure pneumothoraces requiring intervention ranges from 1.6% to 17%.^{59,60} The most important risk factor is underlying chronic obstructive pulmonary disease (COPD).⁶¹ Hemoptysis occurs in 5% to 10% of cases and is usually self-limited. Massive hemoptysis is rare with the use of 20-gauge or smaller needles.^{62,63} Relative contraindications to transthoracic biopsy, therefore, are the presence of severe COPD, a bleeding disorder, contralateral pneumonectomy, and severe pulmonary hypertension. When successful, the results of percutaneous transthoracic biopsy are positive in patients with lung cancer in roughly 90% of cases, with a low false-positive rate of less than 2%.⁶⁴ However, false-negative results can be frequent, so all results should be considered indeterminate unless a specific benign diagnosis is made.

Cervical Mediastinoscopy

Accurate assessment of the mediastinum is paramount as mediastinal lymph node involvement by metastatic carcinoma strongly influences treatment decisions. Until the development of EBUS, cervical mediastinoscopy was the most accurate pre-resection method of staging the mediastinum in lung cancer. Described by Carlens in 1959, mediastinoscopy is performed with a rigid, lighted scope placed in the avascular, pretracheal space to access the superior mediastinum.⁶⁵ Its efficacy is well established, with a pooled procedural sensitivity of 81% and a specificity of 100% in a recent meta-analysis of 5687 patients.^{65a} A negative mediastinoscopy also predicts a high rate of complete resection at thoracotomy. Luke and colleagues⁶⁶ demonstrated that of 590 patients with a negative mediastinoscopy, 93% had complete tumor resection. Cervical mediastinoscopy is an outpatient procedure that is extremely safe. In a review of 2137 patients, Hammoud and coworkers⁶⁷ reported overall morbidity and mortality rates of 0.6% and 0.05%, respectively.

In the pre-EBUS era, the indications for mediastinoscopy were often debated and routine mediastinoscopy was controversial. Most thoracic surgeons agreed that mediastinoscopy should be performed for the following: (1) lymph node enlargement greater than 1 cm in the short axis on CT, (2) hypermetabolic uptake on PET, and (3) possible enrollment into induction therapy protocols. Relative indications included the presence of T2 or T3 tumor or poor prognostic tumor histologies such as large cell carcinoma.⁶⁸ Those who supported the practice of routine mediastinoscopy emphasized its low complication rate and high level of accuracy, the high rate of complete resection after a negative mediastinoscopy, the relatively low sensitivity of CT, the prevalence of nodal disease even in T1 tumors (Table 16-3), and the ability to select patients who might benefit from induction therapy. During the past decade, the combination of PET-CT and EBUS-TBNA has gradually replaced mediastinoscopy in the staging of NSCLC. However, mediastinoscopy remains appropriate in situations where EBUS-TBNA samples are inadequate for diagnosis or for tumor molecular profiling.

Left Anterior Mediastinotomy and Extended Cervical Mediastinoscopy

One limitation of mediastinoscopy can be in the setting of a left upper lobe cancer, in which aortopulmonary window and para-aortic lymph nodes (levels 5 and 6) may

TABLE 16-3 Prevalence of Nodal Metastases in Clinical T1 Non-Small Cell Lung Cancer

Author (ref)	Patients (N)	Node+ (%)	N1 (%)	N2 (%)	Skip N (%)
Ishida et al ⁸⁷	221	28	9	19	28

Oda et al ⁹⁰	524	22	8	14	51
Graham et al ⁹¹	86	29	19	10	34

need to be sampled. In this situation, there are two options for surgical staging. Levels 5 and 6 mediastinal lymph nodes can be accessed from a left anterior or parasternal approach, as described by McNeill and Chamberlain.⁶⁹ A transverse incision is placed over the second rib, and the costal cartilage is removed. The retrosternal extrapleural space is entered by blunt dissection, and the para-aortic space is explored. Modifications of the procedure include preservation of the internal mammary vessels, use of the mediastinoscope for better visualization, and preservation of the cartilaginous rib. In three reported series totaling 194 patients with left upper lobe cancers who underwent a Chamberlain procedure, 38% (73 of 194) had positive biopsy results, and resectability in those patients with a negative anterior mediastinotomy was 95%.⁷⁰ As with cervical mediastinoscopy, morbidity and mortality rates in previously reported series are low—8% and 0%, respectively.

Another surgical approach to the anterior mediastinum in left upper lobe cancers is extended mediastinoscopy, described by Ginsberg and associates.⁷¹ After a pathologically negative standard cervical mediastinoscopy, the mediastinoscope is withdrawn, and blunt digital dissection is used to create a window between the innominate and left carotid arteries posterior to the innominate vein. The mediastinoscope is reinserted and advanced along the anterolateral surface of the aortic arch into the node-containing fat pad. Extended mediastinoscopy should be avoided in patients with a dilated or calcified aortic arch or previous sternotomy. Because of the challenging nature of the dissection required for extended mediastinoscopy and the development of other minimally invasive alternatives to accessing the aortopulmonary window, such as EUS and video-assisted thoracic surgery, extended mediastinoscopy is no longer widely performed.

Scalene Node Biopsy

Scalene node biopsy is used to assess suspect nodes in the supraclavicular fossa, identified by either palpation or imaging (specifically, PET-CT). If there are palpable nodes in the supraclavicular fossa, a fine-needle aspiration (FNA) in the office is often sufficient. If an FNA is nondiagnostic, or metastatic disease is suspected on imaging, formal excision of the fat pad may be performed. A 3- to 4-cm incision is placed over the insertion of the sternocleidomastoid muscle parallel to the clavicle. Dissection is performed between the clavicular and sternal heads, exposing the scalene fat pad on top of the scalenus anterior muscle. Care must be taken to preserve the phrenic nerve lying posterior on the scalenus anterior muscle. Scalene node biopsy can also be done during a mediastinoscopy using a single incision. Lee and Ginsberg reported that 15.4% of patients (6 of 39) with positive N2 disease had positive scalene nodes as well, indicating N3 disease.⁷²

Video-Assisted Thoracic Surgery

Video-assisted thoracic surgery (VATS), now performed with a videothoracoscope, is a valuable tool for the

diagnosis and staging of NSCLC. It requires general anesthesia and a patient who can tolerate single-lung ventilation. With the patient in a standard lateral decubitus position, the thoracoscope and endoscopic instruments are inserted through one or more operating ports placed via small intercostal incisions. The entire hemithorax can be explored, including the hilum, mediastinum, visceral and parietal pleural surfaces, and chest wall. The principal use of VATS has been to perform the excisional biopsy of peripheral lung nodules for the diagnosis of primary lung cancer or to rule out synchronous or metastatic disease.⁷³ It can be used to evaluate mediastinal lymph nodes—in particular, those inaccessible by cervical mediastinoscopy (anterior, aortopulmonary, para-aortic) or anterior mediastinotomy (hilar, inferior pulmonary ligament).^{74,75} Several studies have shown that the sensitivity and accuracy of VATS are almost 100% for diagnosis and staging of lung cancer, with minimal morbidity and mortality.

Thoracotomy

With the myriad of accurate, less invasive diagnostic methods available, more than 95% of tumors can be characterized without thoracotomy. Exploratory thoracotomy, however, still allows the most thorough assessment of the primary lesion, the pleural space, and the ipsilateral mediastinal lymph nodes. The tumor is typically biopsied with a Tru-Cut needle, and the local extent and status of the mediastinal lymph nodes are assessed while the pathologists analyze the specimen by frozen section.

METASTATIC WORKUP

Approximately 40% of patients with newly diagnosed lung cancer are found to have extrathoracic metastases. Identifying these patients is critical to avoid unnecessary thoracotomy and a delay in appropriate systemic therapy. Currently, the standard multiorgan imaging techniques used to rule out the most common metastases in patients with NSCLC (adrenal, liver, brain, bone) are CT of the chest and upper abdomen, CT or MRI of the brain with contrast, and whole-body PET-CT.

Who should undergo evaluation for distant metastatic disease? There are few prospective randomized trials of extrathoracic imaging for NSCLC. It is well accepted that patients who have certain symptoms, abnormal physical findings, or laboratory abnormalities are at increased risk of having metastatic disease. Silvestri and coauthors showed in a large meta-analysis that a positive clinical evaluation was associated with a roughly 50% rate of abnormal scans.⁷⁶ These results underscore how critical the findings of the initial history, physical examination, and laboratory tests are in guiding subsequent workup. Patients with a positive clinical evaluation (Table 16-4) should undergo multiorgan scanning.

What about asymptomatic patients? Routine multiorgan imaging in patients without symptoms or signs is controversial. Several studies have shown that routine preoperative scanning in asymptomatic patients is

TABLE 16-4 Clinical Evaluation for Metastatic Disease

Clinical Evaluation	Finding
Symptoms	Constitutional: weight loss > 5% of body weight, malaise Musculoskeletal: focal skeletal pain Neurologic: headache, seizure, mental status or personality changes
Physical signs	Focal neurologic deficit Supraclavicular lymphadenopathy Hoarseness Superior vena cava syndrome Bony tenderness Skin or soft tissue mass Hepatomegaly
Laboratory tests	Anemia Elevated liver function tests Hypercalcemia

associated with a low percentage (3% to 10%) of positive results, with silent metastases found in 2.7% to 15%.⁷⁷ In their meta-analysis, Silvestri and colleagues⁷⁶ calculated the probability that a scan will be negative if the clinical evaluation is negative (i.e., the negative predictive value of the clinical evaluation). For CT of the abdomen or brain, and for bone scan, the negative predictive values were 94%, 95%, and 89%, respectively. The only prospective, randomized trial that compared routine multi-organ scanning with chest CT and mediastinoscopy in asymptomatic patients with clinically operable lung cancer showed no statistically significant difference in the rate of unnecessary thoracotomy, postoperative recurrence, or overall survival.⁷⁸ Despite this, more recent data have shown whole-body PET and PET-CT to be invaluable in disclosing non-central nervous system metastatic disease in up to 10% to 20% of cases missed by standard methods.^{26,79,80} On this basis, PET-CT should be considered a standard staging modality in all cases of biopsy-proved or suspected lung cancer, and it obviates the need for bone scan as well.

In addition, some authors have reported that more locally advanced lesions (T3 or N2) have a higher rate of asymptomatic distant metastases.^{81,82} Others have shown that adenocarcinomas have a higher rate of asymptomatic cerebral metastases than squamous carcinomas.^{77,83} However, the evidence to support routine brain imaging in the evaluation of potentially resectable NSCLC is scant and is based primarily on retrospective series. MRI with or without intravenous gadolinium is considered the optimal imaging study. A generally accepted approach is to add brain MRI to CT and PET-CT for evaluation of clinically higher stage tumors (stages II and III) but not for stage I tumors where the frequency of asymptomatic brain metastases is only about 5%.⁸⁴⁻⁸⁶

Based on available information, it is appropriate for all patients with established or suspected lung cancer to undergo high-resolution, contrast CT of the chest and whole-body PET-CT. Selected patients should undergo brain MRI. Multiorgan scanning should be considered for (1) any patient with a positive clinical evaluation

(symptoms, signs, blood work), (2) patients with locally advanced disease (stage IIIA) being considered for multimodality therapy, and (3) patients with earlier stage disease (stages I, II) who are marginal operative candidates.

SUMMARY

Lung cancer remains a challenging and deadly disease. Proper diagnosis and staging are critical for determining the best treatment strategy for each patient. The most important components of the workup are the initial history and the physical examination. Numerous noninvasive and invasive techniques can be used to establish an accurate and valid clinical estimate of tumor stage.

Outcome

SUMMARY

This chapter provides an overview of the surgical treatment for lung cancer. The indications for surgery, types and extent of lung resection, and mediastinal lymphadenectomy are reviewed, with an emphasis on recent published evidence and the new international tumor-node-metastasis (TNM) staging system (seventh edition, 2009). Minimally invasive lung resection (see [Chapter 18](#)), tracheal lesions (see [Chapter 8](#)), tumor invading the chest wall (see [Chapter 20](#)), and multimodality approaches (see [Chapter 19](#)) are specifically covered separately.

Lung cancer remains the leading cause of cancer death worldwide, with an estimated 159,480 deaths and 228,190 new cases in the United States in 2013.¹ Complete surgical resection is the treatment of choice for patients with early-stage (stages I and II) and selected locally advanced (stage III) non-small cell lung cancer (NSCLC). Surgery may have a role to play in the following cases as well: NSCLC with isolated adrenal metastasis, isolated brain metastasis, or highly selected small cell lung cancer. Adjuvant chemotherapy has been established as a modality to improve survival in selected resectable NSCLC on the basis of published clinical studies including phase III randomized trials.²⁻⁶ Neoadjuvant therapy (induction chemotherapy or chemoradiotherapy) improves outcome in patients with N2 disease or resectable, locally advanced NSCLC.⁷

HISTORICAL NOTE

The first lobectomy for lung cancer was described by Davies⁸ in 1913-1914; the patient died 8 days after resection, with empyema. As water-sealed drainage system and anesthetic techniques advanced, surgical resection for lung cancer became prevalent. In 1933, Graham and Singer⁹ reported the first successful one-stage pneumonectomy. Since then, the standard operation for lung cancer became pneumonectomy with the technique of individual hilar ligation of the pulmonary vessels and suturing of the bronchus. Around the same time, Churchill and coworkers¹⁰ described their experience of lobectomies with hilar dissections. The technique of segmentectomy for lung cancer was described by Overholt and Langer.¹¹ As refinements progressed, more advanced techniques were developed, including sleeve resection by Price-Thomas¹² in 1956, carinal resection by Mathey and colleagues¹³ and Thompson,¹⁴ and Pancoast tumor resection by Chardak and MacCallum.¹⁵ Grillo and colleagues¹⁶ reported on carinal resection with airway reconstruction in 1963. In 1973, Jensik and colleagues¹⁷ reported a large series of segmental resections as intentional curative procedures for the treatment of bronchogenic carcinoma. Since the early 1990s, as the system of video endoscopy and endoscopic instruments have evolved, video-assisted thoracoscopic surgery (VATS) for major pulmonary resection has continued to develop worldwide.¹⁸ More recently, studies have demonstrated that robot-assisted surgery is a safe and feasible operation for pulmonary resection.^{19,20}

PULMONARY SURGICAL OPERATIONS: INDICATIONS AND TECHNIQUES

Lobectomy

Lobectomy with complete en bloc tumor removal remains the standard surgical procedure in patients with resectable NSCLC. Resections less extensive than lobectomy (i.e., segmentectomy and wedge resection) are chosen in patients with limited pulmonary reserve or, recently, in those with small peripheral tumors without nodal disease for curative intent. The indications for curative-intent sublobar resection are discussed later. On occasion, sleeve lobectomy is required when the tumor protrudes into the mainstem bronchus. A concern with sleeve lobectomy is that it might be an inferior oncologic resection compared with pneumonectomy; however, sleeve lobectomy, compared with pneumonectomy, has demonstrated better long-term outcome, that is, lower morbidity and mortality rates.^{21,22}

Positioning and Incisions

The patient is placed into the lateral decubitus position. Entry into the pleural space via a posterolateral incision is the standard that provides an excellent exposure to the hilum of the lung. The anterior serratus muscle can be mobilized and spared whenever possible. The intercostal muscle, in most cases the fifth intercostal, is cut along the rib both anteriorly and posteriorly to obtain wider rib spreading. Anterior, lateral, or axillary thoracotomies are other alternatives. Occasionally, a hemi-clamshell incision or median sternotomy is selected for extended resection of apical tumors because either provides excellent exposure of the thoracic inlet, superior pulmonary veins, and main pulmonary arteries.

Mobilization and Hilar Dissection

After the pleural cavity is entered, careful inspection of the pleural space is performed. Any pleural fluid is sampled for cytology and culture. All lobes of the lung are then palpated to assess the extent of the disease, to identify unexpected pleural or parenchymal lesions, and to confirm resectability. The inferior pulmonary ligament is incised up to the inferior pulmonary vein, and the mediastinal pleura of the hilum is incised circumferentially to totally mobilize the lung. Care must be taken to prevent injury to the phrenic nerve by electrocautery when the anterior hilum is opened. The posterior views of right and left pulmonary hila are shown in [Figure 17-1](#).

The hilar vascular structures (the main pulmonary artery and the superior and inferior pulmonary veins) are identified and dissected. The fissures between the lobes are often not completely open, so dissection is required to reach the interlobar structures. The incomplete fissures usually necessitate a combination of sharp and blunt dissection. Care must be taken to avoid violation of the tumor if an extension of the tumor from one lobe to another is seen. The interlobar views of right and left lungs are shown in [Figure 17-2](#).

FIGURE 17-1 ■ Posterior views of the right (A) and left (B) pulmonary hila. The mediastinal pleura is opened and the lung retracted anteriorly. (Illustrations by Dennis Wei.)

FIGURE 17-2 ■ The interlobar views of the right (A) and left (B) lungs. The fissures are incised and pulmonary artery branches are exposed. (Illustrations by Dennis Wei.)

Management of Vessels

Once the interlobar pulmonary artery is identified, the segmental arteries are exposed to the appropriate plane by dissecting down onto the pulmonary arterial vascular plane. The fissures can be divided with electrocautery or with a mechanical stapler, depending on the amount of parenchymal tissue to be transected. For division of pulmonary arteries, some surgeons prefer transfixing ligatures (especially for larger vessels), and others apply simple nonabsorbable ligatures. The

mechanical stapler can be also used to divide large vessels. It is preferable to isolate and tape the main pulmonary artery and pulmonary veins for control before starting vessel dissections in the following cases: (1) tumor invasion to the main trunk of the pulmonary artery, (2) tumor involving the roots of segmental arterial branches, or (3) significant inflammatory scarring or adhesions encountered around the pulmonary arteries. Using this technique, the main pulmonary artery and veins can be easily clamped for control if an arterial injury occurs.

The order of division of the vasculature is flexible; however, it is safe to divide pulmonary artery branches, then veins, followed by the bronchus, in most cases. Some prefer to divide veins first to avoid possible tumor cell dissemination into the blood circulation during the manipulation of the lung, but it has not been proven that this maneuver affects long-term outcome. The disadvantage of dividing the pulmonary veins before the artery branches is that the diseased lobe may become congested with retained blood, making the surgery difficult. It is often advantageous to first divide the structure whose absence allows better exposure of the remaining structures. For example, the bronchus can be divided first to obtain better exposure and dissection of the pulmonary artery branches if needed.

Management of Bronchus

After obtaining the proposed bronchial margin by clearing peribronchial lymph nodes of the diseased lobe, bronchial closure is performed with a bronchial stapler. Excessive devascularization of the bronchial stump should be avoided to prevent bronchopleural fistula (BPF). Although closure can be performed by hand-suturing techniques, the stapling technique is faster and equally safe. Before firing the bronchial stapler, the anesthesiologist is asked to inflate the operative lung to confirm no impingement of the main bronchus or other remaining bronchi. Frozen-section pathologic examination of the bronchial margins should be obtained if there is any concern of tumor invasion. For poor-risk patients or those who received induction chemoradiotherapy, the bronchial stump should be covered with pericardial fat pad, pericardium, pleura, or intercostal muscle to minimize the chances of a postoperative BPF. In cases of sleeve lobectomy, cancer-free margins on both proximal and distal bronchial ends should be confirmed by frozen section. For the bronchial anastomosis, two traction stitches are placed on both bronchial ends. Interrupted 4-0 monofilament absorbable sutures are placed on the cartilaginous portion and a running monofilament absorbable suture on the membranous portion without any tension on the bronchial anastomosis.

Placement of Chest Tubes

Chest tubes are placed for evacuation of residual fluid and air to reexpand the residual lung. Another purpose of tube placement is for monitoring of postoperative bleeding. Although there are no standardized rules in terms of the tube size and number, we usually place an apical chest tube and an angled basilar chest tube above the diaphragm (28 Fr).

Pneumonectomy

As anatomic lobectomy has become the standard form of curative resection for bronchogenic carcinoma, pneumonectomy has become less prevalent. Pneumonectomy is reserved for central lesions, traditionally, but even in patients with tumor invasion of the mainstem bronchus or bronchus intermedius, sleeve lobectomy is the

procedure of choice, with acceptable morbidity, mortality, and long-term survival.²³ After careful assessment and patient selection, pneumonectomy is used for patients with centrally located NSCLC that cannot be completely resected using bronchoplastic procedures.

Incision

Posterolateral thoracotomy via the fifth intercostal space is the standard approach because it provides excellent access to both the anterior and the posterior hila. Anterior thoracotomy or muscle-sparing (e.g., anterior serratus muscle or latissimus dorsi muscle) thoracotomy is another option of choice. On entering the pleural cavity, a careful assessment is performed to identify the extent of tumor. This includes bronchoscopic assessment at the time of surgery. The decision to perform pneumonectomy is usually made preoperatively on the basis of the tumor location and the cardiopulmonary reserve; however, occasionally, it is not possible to make a decision before the intraoperative assessment. A lesser resection such as sleeve lobectomy with or without pulmonary arterioplasty should always be considered as long as a complete en bloc tumor resection can be achieved.

Hilar Dissection

Once the need for pneumonectomy is confirmed, the hilum is dissected to identify the main pulmonary artery and the superior and inferior pulmonary veins. After retracting the lung anterosuperiorly, the inferior pulmonary ligament is divided up to the level of the inferior pulmonary vein. The inferior pulmonary vein is exposed and isolated by dissecting surrounding connective tissues. On the right side, a plane between the main pulmonary artery and the superior pulmonary vein should be developed for dissection. On the left side, the superior pulmonary vein resides anterior to the left main bronchus, so a plane for dissection should be found between these structures. The division of the superior and inferior pulmonary veins can be performed by double ligation or stapling. When the tumor involves the pericardial reflection, the pericardium is opened for more proximal vessel isolation, and a vascular clamp is applied across the atrium for division of the pulmonary vein. After division of the vein, the stump is closed with a double-layer nonabsorbable suture.

When the tumor is in close proximity to the proximal pulmonary artery, and thus it is not possible to obtain a sufficient margin to apply a stapler, the pericardium should be opened to obtain additional length for division (Fig. 17-3). On the right side, mobilization of the superior vena cava is often required to encircle the proximal right main pulmonary artery. On the left side, division of the ligamentum arteriosum produces additional length for division of the left main pulmonary artery proximally. During this maneuver, special attention should be paid to avoiding injury to the left recurrent laryngeal nerve, if the nerve is not involved by the tumor. Dissecting proximally after opening the pericardium at its reflection, one can divide the left pulmonary artery at its origin. It is important not to impinge on the right pulmonary artery

FIGURE 17-3 ■ The anterior intrapericardial views of the right (A) and left (B) hila. (Illustrations by Dennis Wei.)

when applying traction to staple the left main pulmonary artery.

Management of Bronchus

The division of the mainstem bronchus should be performed as proximally as possible (3 to 5 mm from the carina) to avoid creating an unnecessarily long bronchial stump. On the right side, the carina and the anticipated point of bronchial division is often visualized easily. The division of the left mainstem bronchus requires some traction on the bronchus, because the carina is poorly visualized from the left side. Peribronchial tissues and lymph nodes around the bronchus are cleared to better expose the bronchus, but an excessive devascularization should be avoided to preclude poor healing that could lead to postoperative BPF. In patients who received induction radiotherapy, the stump of the right main bronchus should be covered by a pericardial fat pad, mediastinal pleura, pericardium, intercostal muscle flap, or even omentum. Although it is generally desirable to protect the right main bronchial stump, it is not always necessary on the left side because the left main stump retracts into mediastinal tissues after division. Darling and colleagues²⁴ reported the rates of BPF were approximately 13% on the right side and 5% on the left side, with 8% overall.

Management of the Postpneumonectomy Space

The goal of management of the postpneumonectomy space is to normalize (i.e., reposition) mediastinum to the midline. To accomplish this, some leave a small chest tube to evacuate a measured quantity of air immediately after surgery in the operating room, and then remove the tube, whereas others leave a chest tube with balanced

pneumonectomy drainage systems (e.g., Pleur-evac [Teleflex Medical, Research Triangle Park, NC] balanced pneumonectomy drainage system) to avoid mediastinal shift while maintaining normal pressures. Alternatively, a chest tube can be left clamped and intermittently unclamped briefly to reposition the mediastinum. In any case, negative pressure to the chest tube must not be applied because it may cause a significant mediastinal shift to the operative side.

Sublobar Resection (Segmentectomy and Wedge Resection)

Sublobar resection was originally developed for the surgical management of infectious lung diseases such as tuberculosis and bronchiectasis, in which bilateral or multisegmental disease is frequently seen. For the treatment of NSCLC, this has generally been the option for patients with poor pulmonary function who may not tolerate anatomic lobectomy, because limited resections have demonstrated a higher local recurrence rate and worse long-term outcome than anatomic lobectomy.²⁵ However, recent evidence suggests that sublobar resection, especially anatomic segmentectomy, may in fact be the surgical procedure of choice, not only for patients with poor cardiopulmonary reserve but also for those with early stage NSCLC at low risk.²⁶ In general, anatomic segmentectomy is preferred over simple wedge resection to clear the lymphatics draining the tumor bed. Generous wedge resection with cancer-free margins may be acceptable for small, peripheral, “nonsolid” bronchioalveolar carcinoma.²⁷ Sampling or formal dissection of hilar and mediastinal lymph nodes with intraoperative frozen-section pathology should be performed to confirm any nodal disease. If proven positive for nodal disease intraoperatively, the surgical resection should be converted to anatomic lobectomy whenever possible.

Surgical Principles

Because the landmark of a diseased segment used to guide resection is its bronchus, identification of the bronchus of the diseased segment is a key step. The division of segmental structures tends to begin with the segmental arterial branch, because this often allows good exposure of the segmental bronchus, which runs along with the segmental artery. The segmental vein is best divided last, after identification of the intersegmental plane. Intersegmental veins, the venous drainage of adjacent segments, are usually preserved. The separation at the intersegmental lung parenchymal plane is performed with differential lung deflation and inflation. First, the segmental bronchus of the diseased segment is clamped in a deflated state. Then the lung is inflated, and the demarcation line can be identified because the diseased segment remains airless while other parts of the lung are expanded. Alternatively, the lung is expanded first, followed by clamping the bronchus of the diseased segment; then the lung is deflated to demarcate the diseased segment that remains expanded. Manual monofilament absorbable interrupted suturing (4-0 polydioxanone [PDS] or Maxon) is usually used for the bronchial closure. Stapling may be performed if sufficient length of the diseased segmental bronchus is available. In this case, care must be taken to

avoid compromising adjacent segmental bronchi. Blunt or sharp dissection of the intersegmental plane is traditionally performed by scissors, a sponge on a stick, or the surgeon's fingers. Small bridging veins or bronchi are individually clipped or ligated for division. Stapling the intersegmental plane is also applicable and desirable, and this is achievable if the resection is extended into an adjacent segment to achieve an adequate margin from the tumor. Any air leaks from the dissecting plane are controlled by nonabsorbable suturing. Various types of segmentectomy are shown in Figure 17-4.

The use of wedge resection as a surgical procedure for primary lung cancer should be strictly limited to small, peripheral, early-stage NSCLC. Although wedge resection is often accomplished by VATS, it is often difficult to assess the interlobar lymph nodes. Whenever there is any doubt about the resection margins, the procedure should be converted to anatomic segmentectomy.

Mediastinal Lymph Node Dissection

Rationale

Recent advances in mediastinal staging with computed tomography (CT), positron emission tomography (PET), and endobronchial ultrasound-guided fine-needle

FIGURE 17-4 ■ Segmental resections of the lung. **A**, Right lung. Upper lobe: posterior and apical segmentectomies. Lower lobe: superior segmentectomy. **B**, Left lung. Upper lobe: lingular and superior division segmentectomies. Combined segmentectomies of apical-posterior (upper lobe) and superior (Sup.) segments (lower lobe). LLL, Left lower lobe; LUL, left upper lobe; RLL, right lower lobe; RML, right middle lobe; RUL, right upper lobe. (From Jensik RJ, Faber LP, Milloy FJ, et al: Segmental resection for lung cancer. A fifteen-year experience. *J Thorac Cardiovasc Surg* 66:563–572, 1973.)

aspiration (EBUS-FNA) have improved diagnostic accuracy.^{28,29} However, there is no doubt that intraoperative mediastinal lymph node staging remains the gold standard, and it is an integral part of the surgical treatment of lung cancer to determine accurate nodal (N) status, which is a significant outcome predictor.³⁰ Generally, *lymph node sampling* indicates the removal of macroscopically abnormal lymph nodes. When biopsies are performed from all lymph node stations, it is said to be *systematic sampling*. If systematic removal of all the mediastinal tissue containing lymph nodes within anatomic landmarks is performed, it is referred to as *complete lymph node dissection*. Bilateral mediastinal and cervical lymph node clearance is referred to as *extended lymph node dissection*.³¹ It has been a subject of controversy as to whether complete lymph node dissection is superior to systematic sampling in diagnostic accuracy and long-term survival. These issues are discussed later. The classification and graphic representation of lymph node levels for lung cancer staging by the American Joint Committee on Cancer (AJCC) and the Union for International Cancer Control (UICC)³² are shown in Figure 17-5.

Techniques

Mediastinal lymph node dissection (MLND) is almost always accompanied by lung resection for lung cancer, so the procedure is most frequently performed via a posterolateral thoracotomy. It can also be achieved via median sternotomy, anterior thoracotomy, or, more recently, VATS incisions. Although the surgical procedure and extent of MLND may vary from surgeon to surgeon, dissection of stations 2R, 4R, 7, 8, 9, and 10R for the right side and stations 5, 6, 7, 8, 9, and 10L on the left side is generally accepted. On the right side, the superior mediastinum bordered by the superior vena cava anteriorly, the trachea posteriorly, the innominate artery superiorly, and the azygos vein inferiorly, is dissected for lymphadenectomy. After incision of the mediastinal pleura, the mediastinal fat pad is dissected from the posterior aspect of the superior vena cava and the anterolateral surface of the trachea. One or two small draining veins are frequently seen from the mediastinal fat pad into the superior vena cava, and they are ligated or simply clipped. Right station 2 (2R) nodes are located between the cephalic border of the aortic arch and the cephalic border of the right innominate artery. Right station 4 (4R) nodes are found between the cephalic border of the aortic arch and the origin of the right upper lobe bronchus. Lymph nodes at station 3 posterior (3p) are dissected between the esophagus and the membranous portion of the trachea, and at station 3 anterior (3a) are taken anterior to the superior vena cava (anterior to the right phrenic nerve) where necessary. Right station 10 (10R) nodes are dissected along the anterior border of the right bronchus distal to the pleural reflection.

To expose the subcarinal lymph nodes (7), the lung is retracted anteriorly. After incision of the mediastinal pleura along with the anterior border of the esophagus, the subcarinal fat pad is dissected from the medial border of the right main bronchus laterally, the anterior aspect

of the esophagus posteriorly, and the pericardium anteriorly. The attachments between the main bronchus and the fatty tissues containing subcarinal nodes are freed. The bronchial arterial branches running into the fat tissues are clipped before division to avoid unnecessary bleeding. The inferior pulmonary ligament nodes (9) are easy to dissect, and the paraesophageal nodes (8) are taken if they are present. On the left side, aortopulmonary (5 and 6) and subcarinal (7) nodes are dissected. For the upper mediastinal node dissection, the mediastinal pleura is incised just above the left main pulmonary artery, all the way up to the cephalic border of the aortic arch, midway between the phrenic nerve and the vagus nerve. Para-aortic (6) nodes are dissected from the phrenic nerve posteriorly and the ligamentum arteriosum anteriorly, and subaortic (5) nodes are removed posterior to the ligamentum arteriosum. During dissection, small arteries or veins should be controlled by ligation or clipping to avoid any thermal injury of the phrenic, vagus, and recurrent laryngeal nerves by electrocautery. Subcarinal (7) nodes can be removed in the same way as on the right side.

SURGICAL TREATMENT OF NON-SMALL CELL LUNG CANCER

Surgical resection is generally considered in patients with stage I or II NSCLC. Those with locally advanced stage IIIA or IIIB NSCLC are usually treated with chemotherapy and radiotherapy. However, stages IIIA and IIIB represent heterogeneous groups of patients, and select patients will benefit from surgical resection.

The decision regarding surgical intervention is based on several variables, including the extent of disease (both T and N factors), age, cardiopulmonary reserve, performance status, and comorbid risk factors. Induction or adjuvant (postsurgical) chemotherapy with or without radiotherapy is offered to surgical candidates with locally advanced NSCLC. Recently, adjuvant or neoadjuvant chemotherapy has been also offered to patients with early-stage resectable NSCLC in clinical trial settings, and the combined approach appears to prolong survival.

The UICC and the AJCC published the seventh edition of the TNM classification for lung cancer in 2009.³³

The recently revised TNM descriptors are shown in Table 17-1. Specific surgical issues related to each stage (T, N, and M) are discussed here.

T Category: T1 and T2

T1 and T2 tumors are subcategorized in the seventh edition of the TNM staging according to the proposals by the IASLC Lung Cancer Staging Project.³⁴ The changes in the T classification in the T1 and T2 categories are as follows: (1) T1 is subcategorized into T1a, if the tumor is 2 cm or less, and T1b, if the tumor is greater than 2 cm but not greater than 3 cm; (2) T2 tumors are greater than 3 cm, and they are T2a if equal to or less than 5 cm, and T2b if greater than 5 cm and equal to or

FIGURE 17-5 ■ The International Association for the Study of Lung Cancer (IASLC) lymph node map. (From Rusch VW, Asamura H, Watanabe H, et al: The IASLC lung cancer staging project: a proposal for a new international lymph node map in the forthcoming seventh edition of the TNM classification for lung cancer. *J Thorac Oncol* 4:568–577, 2009.)

less than 7 cm. Tumors greater than 7 cm are in the T3 category (see Table 17-1).

For the T1 and T2 categories, the surgical procedure of choice is essentially the same if patients are medically fit and have good cardiopulmonary reserve; anatomic lobectomy is the preferred mode of resection.³⁵ However, recent refinements of prognostication suggest that sublobar resection (segmentectomy or wide wedge resection)

may be performed on patients with small, peripheral, early-stage NSCLC, or those older than 71 years without jeopardizing the clinical outcome.³⁶ Additional multicenter trials comparing lobectomy with lesser resections are under way.^{37,38} On another front, a growing body of evidence suggests that surgical resection alone is not adequate for the treatment of large-sized NSCLC without any nodal disease.²

TABLE 17-1 Definitions for T, N, and M Descriptors by the International Association for the Study of Lung Cancer (IASLC)**T (Primary Tumor)**

TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor $\leq$ 3 cm in greatest dimension, surrounded by lung or pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)*
T1a	Tumor $\leq$ 2 cm in greatest dimension
T1b	Tumor $>$ 2 cm but $\leq$ 3 cm in greatest dimension
T2	Tumor $>$ 3 cm but $\leq$ 7 cm or tumor with any of the following features (T2 tumors with these features are classified T2a if $\leq$ 5 cm) Involves main bronchus, $\geq$ 2 cm distal to the carina Invades visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor $>$ 3 cm but $\leq$ 5 cm in greatest dimension
T2b	Tumor $>$ 5 cm but $\leq$ 7 cm in greatest dimension
T3	Tumor $>$ 7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in the main bronchus $<$ 2 cm distal to the carina* but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina; separate tumor nodule(s) in a different ipsilateral lobe

N (Regional Lymph Nodes)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)

M (Distant Metastasis)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural (or pericardial) effusion [†]
M1b	Distant metastasis

*The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximally to the main bronchus, is also classified as T1.

[†]Most pleural (and pericardial) effusions with lung cancer are due to tumor. In a few patients, however, multiple cytopathologic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and is not an exudate. Where these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient should be classified as T1, T2, T3, or T4.

Adapted from Goldstraw P, Crowley J, Chansky K, et al: *The IASLC lung cancer staging project: proposals for the revision of the TNM stage groupings in the forthcoming (seventh) edition of the TNM classification of malignant tumours*. *J Thorac Oncol* 2:706–714, 2007.

Sublobar Resection versus Lobectomy for Node-Negative, Small-Size Non-Small Cell Lung Cancer

Jensik and coworkers¹⁷ reported their 15-year experience of segmental resections of peripheral lung cancer as a curative-intent procedure in 1973. The 5-year survival rate of 69 patients who underwent curative resections by segmentectomy was 56%. Of these, six (9%) developed local recurrence in the primary lobe. The authors concluded that segmentectomy can be a valid procedure for selected, peripherally located lung cancer. In the early 1980s, the Lung Cancer Study Group (LCSG) performed a multicenter randomized clinical trial of lobectomy versus a lesser resection by wedge or segmentectomy in T1N0 NSCLC in patients with small peripheral tumors, and the report suggested a threefold increase

in the incidence of local recurrence in patients treated by resections smaller than lobectomy.²⁵ Therefore, the authors recommended that the use of sublobar resection should be limited to poor-risk patients with compromised pulmonary function.

However, more recent evidence suggests that radical, curative-intent sublobar resection can be offered for clinical T1N0 NSCLC even in good-risk patients. The survival outcome and locoregional recurrence rates of anatomic segmentectomy in comparison with lobectomy are summarized in Table 17-2.^{25,39-42} Although most of the evidence is from retrospective studies comparing the outcome of segmentectomy with that of lobectomy, several key factors have been identified to obtain optimal results by anatomic segmentectomy. The factors include (1) surgical margins, (2) tumor size, and (3) lymph node assessment.

TABLE 17-2 Long-Term Outcome and Local Recurrence Rate of Sublobar Resection in Comparison to Lobectomy in Patients with Early-Stage Non–Small Cell Lung Cancer

Author (Year)	N (Sublobar/ Lobectomy)	Stage	<i>Sublobar Resection versus Lobectomy</i>	
			Local Recurrence (%)	5-Year Survival (%)
Ginsberg, Rubenstein ²⁵ (1995)	125/122	cT1N0	6.3 vs. 2.1*	83 vs. 89
Koike et al ³⁹ (2003)	74/159	cT1N0	2.7 vs. 1.3	89 vs. 90
Fernando et al ⁴⁰ (2005)	124/167	pT1N0	17.5 vs. 10.0 (tumor size < 2 cm)	56 vs. 85 months (MS)
			4.4 vs. 3.5 (tumor size, 2–3 cm)	45 vs. 70 months* (MS)
Okada et al ⁴¹ (2006)	305/262	cT1N0	4.9 vs. 6.9	90 vs. 90
Okumura et al ⁴² (2007)	55/187	pT1N0†	NS	83 vs. 81

*Statistically significant.

†Large cell carcinoma excluded.

c, Clinical; NS, not stated; MS, median survival; p, pathologic.

It is clear that positive surgical margins must be avoided to achieve complete resection; however, it remains unresolved as to what is the optimal adequate surgical margin (i.e., the distance from the tumor to the cut margin) for localized tumors in the setting of segmentectomy. Sawabata and colleagues⁴³ conducted a prospective study to define optimal surgical margins in excision of NSCLC. In the study, the surgical margins were microscopically 100% negative for malignancy when the margin distance was greater than 20 mm or when the resected tumors had a margin distance greater than the maximum tumor diameter (a margin-to-tumor size ratio > 1). Schuchert and coworkers⁴⁴ reported that the local recurrence rate was significantly higher in patients with a margin-to-tumor ratio less than 1 than in those with the ratio greater than 1 (25% versus 6.2%). In the study, the mean surgical margin in patients with local recurrence was 12.8 mm and the margin in those without local recurrence was 18.6 mm. Therefore, lobectomy or extended segmentectomy should be performed when an adequate surgical margin (preferably 2 cm) cannot be obtained, especially if tumors are located centrally. Intraoperative pathologic assessment of surgical margins should generally be performed to confirm the margins.

Tumor size is also an important factor when segmental resection is considered. A large tumor size is associated with increased risk of local recurrence and distant metastasis. Fernando and colleagues reported that there was no difference in survival between sublobar resection and lobar resection groups when the tumor size was smaller than 2 cm in pathologic T1N0 NSCLC, whereas the median survival was significantly better in the lobar resection group when tumor size was greater than 2 cm (68.7 versus 50.6 months).⁴⁰ Okada and colleagues⁴⁵ reported the 5-year cancer-specific survivals of patients with pathologic stage I disease with tumors of 2 cm or less and 2.1 to 3 cm in diameter were similar: 92.4% and 87.4% after lobectomy, and 96.7% and 84.6% after segmentectomy, respectively. On the other hand, in patients with a tumor greater than 3 cm in diameter, survivals were significantly worse in the segmentectomy group than in the lobectomy group (62.9% versus 81.3%). Bando and colleagues⁴⁶ reported a higher locoregional recurrence rate of segmentectomy in patients with tumors 2.1 to 3 cm than in those with tumors 2 cm or smaller. In the report by Schuchert and associates,⁴⁴ recurrence was observed more frequently

in stage IB patients than in stage IA patients. Jones and coworkers⁴⁷ reported no locoregional recurrence in 43 patients with pathologic T1N0 NSCLC who underwent segmentectomy. El-Sherif and colleagues⁴⁸ recently reviewed their experience of sublobar resection versus lobectomy and demonstrated that the disease-free survival rate of sublobar resection was equivalent to that of lobectomy in patients with stage IA NSCLC, but in those with stage IB NSCLC, survival was worse in the sublobar resection group. Several recent series have also reported comparable long-term outcomes of segmentectomy and lobectomy in small (tumor size, <2 cm) T1N0 NSCLC.^{39,41,49} Based on the current evidence, patients with early-stage small NSCLC (tumor size, preferably ≤2 cm) may undergo anatomic segmentectomy if negative nodal disease is confirmed.

Intraoperative lymph node assessment is an integral part of sublobar resection. Miller and colleagues⁵⁰ evaluated the frequency of lymph node metastasis in patients who underwent resection of NSCLC 1 cm or less. The tumors were located in the periphery in 89 patients, centrally in 3, and endobronchially in 8. Of these, seven (7%) had lymph node metastasis (N1 = 5 and N2 = 2). In the prospective nonrandomized trial of sublobar resection reported by Okada and colleagues,⁴¹ of 305 patients with clinical T1 (tumor size, <2 cm) N0 NSCLC who were assigned to undergo sublobar resection, 20 (7%) were found to have lymph node metastasis (N1 = 11 and N2 = 9) intraoperatively, so the procedure was converted to lobectomy. Therefore, even for tumors smaller than 1 cm, intraoperative hilar and mediastinal lymph node sampling or dissection is recommended whenever sublobar resection is performed.

Wedge resection has appeared to be suboptimal for the surgical treatment of lung cancer except for localized, small-size pure bronchioloalveolar carcinoma because of a higher local recurrence rate. Landreneau and associates⁵¹ documented high local recurrence rates in patients with T1N0 NSCLC who underwent wedge resection (wedge versus lobectomy: 24% versus 9%). Sienel and coworkers⁵² analyzed local recurrence rates in patients with pathologic T1N0 NSCLC who underwent either segmentectomy or wedge resection. Segmentectomies were followed by systematic lymph node dissection, and wedge resections by lymph node sampling. The local recurrence rate was significantly higher in the wedge

resection group than in the segmentectomy group (55% versus 16%), and the difference of recurrence rates was significant even in patients with tumors 2 cm or less (40% versus 11%). The observed higher locoregional recurrence rates may be partly explained by an inadequate lymph node assessment, because sampling of interlobar lymph nodes or segmental hilar nodes is often impractical or impossible, resulting in the missing of positive nodes and false downstaging. Wedge resection may also leave draining lymphatic vessels containing cancer cells behind in the residual diseased segment, thus increasing the risk of local recurrence. Therefore, anatomic segmentectomy, but not wedge resection, is recommended for patients with early-stage small NSCLC when sublobar resection is considered. If anatomic segmentectomy might not be tolerated because of poor cardiopulmonary reserve, wedge resection combined with radiotherapy or brachytherapy could be an alternative approach to reduce the risk of local recurrence.^{40,53}

Although much of the evidence for sublobar resection is from retrospective studies, two large-scale prospective randomized trials are currently under way to obtain solid evidence of sublobar resection for stage IA, peripheral NSCLC. Both the Cancer and Lymphoma Group B trial (CALBG 140503)³⁷ and the Japan Clinical Oncology Group and the West Japan Oncology Group trial (JCOG0802/WJOG4607L)³⁸ aimed to recruit more than 1000 cases. The difference between the studies is that the former study allows both segmentectomy and wedge resection for the experimental arm, but the latter Japanese study specifies only segmentectomy for the sublobar resection arm.

T Category: T3

The T3 category includes (1) tumors greater than 7 cm; (2) additional nodules in the primary lobe; (3) tumors of any size invading the chest wall, diaphragm, mediastinal pleura, or parietal pericardium; (4) tumors in the main-stem bronchus less than 2 cm from the carina without invading the carina; and (5) tumor-associated atelectasis or obstructive pneumonitis of the entire lung (see [Table 17-1](#)). Some of these subsets are discussed with respect to their specific surgical considerations later.

Tumors Invading the Chest Wall

Technical details and the outcome of this subset are reviewed in [Chapter 20](#). NSCLC invading the chest wall is usually peripheral in location, so mediastinal lymph nodes are less likely to be involved. The degree of chest wall involvement with tumor varies from the parietal pleura to the muscles and ribs of the chest wall. Those with NSCLC involving the chest wall, but without mediastinal node disease, are good candidates for surgical treatment whenever medically fit. Postoperative mortality has continued to be reduced, in recent reports ranging from 0% to 6.3%.⁵⁴⁻⁶⁰ In general, factors affecting long-term survival include (1) completeness of resection,^{54,56,60} (2) extent of invasion of the chest wall,^{55,56,60} and (3) nodal status.^{54,56,57,59,60} In patients with incomplete resection (macroscopic or microscopic disease) or unresectable

tumors, the 5-year survival was essentially zero.^{54,60} It is a matter of controversy as to whether en bloc (full-thickness chest wall) resection is necessary for all depths of tumors invading the chest wall, but some authors advocate a full-thickness resection to achieve complete tumor clearance.^{56,57,59} A large study of surgically resected T3 NSCLC was recently published by Kawaguchi and coworkers from Japan.⁶¹ In the study, 407 patients having chest wall invasion had 5-year survival of 43.2%. The roles of chemotherapy and radiotherapy for this group of patients are still uncertain and clearly require further investigation.⁵⁹

Superior Sulcus Tumors

Superior sulcus tumors (Pancoast tumors) are a unique subset of carcinomas of the lung, invading the thoracic inlet. Because of the close proximity to thoracic inlet structures, the tumors often invade adjacent tissues early, with symptomatic consequences. In case of tumor invasion to the posterior compartment of the thoracic inlet, involvement of the lower brachial plexus, particularly the T1 nerve root, is common. Shoulder and arm pain radiating to the inner aspect of the upper arm (T1) or the ulnar distribution in the fourth and fifth fingers of the hand (C8), or both, are commonly seen in these cases. Extension to the stellate ganglion with consequent Horner syndrome, or extension to the ribs or vertebrae, is also observed. Tumors invading the anterior compartment of the thoracic inlet may involve the subclavian vessels.

Advances in surgical techniques and combined-modality approaches recently led to the conduct of two prospective multicenter phase II clinical trials, where induction chemoradiotherapy was performed followed by surgical resection in patients with superior sulcus NSCLC.^{62,63} The North American Intergroup trial (Southwest Oncology Group 9416, INT 0160) report by Rusch and colleagues⁶² suggested that both T3N0-1 and T4N0-1 tumors benefit from preoperative chemoradiation with high response rates by pathologic examination (61% with complete pathologic response or minimal microscopic tumor) and high complete resection rates (76% overall, and 94% of patients who underwent thoracotomy). The median survival was 33 months for all patients, and 94 months for the patients who achieved an R0 resection. Kunitoh and coworkers⁶³ reported mature results of induction chemoradiotherapy followed by surgical resection in patients with T3 ($n = 56$) or T4 ($n = 20$) NSCLC (Japan Clinical Oncology Group Trial, JCOG 9806). Of these, 57 patients (76%) underwent surgical resection and, again, a high R0 resection rate (68% overall, and 90% of patients who received surgical resection) was achieved. The overall 5-year survival rate was 56%. In both studies, the pattern of cancer recurrence was predominantly distant, and the brain is the leading organ of relapse. In the INT 0160 trial, 19 of 57 patients (41%) who developed recurrence had brain metastasis only, and 5 of 39 patients (13%) did so in the JCOG 9806 trial. On the other hand, the MD Anderson Cancer Center reported a prospective phase II study of upfront surgery followed by chemotherapy (cisplatin and etoposide) and radiotherapy (50-60 Gy) for superior

sulcus tumors.⁶⁴ The study demonstrated overall survival rates of 50% at 5 years and 45% at 10 years after the treatment. Interestingly, as a part of the study protocol, 11 of 32 underwent prophylactic cranial irradiation (PCI, 25 Gy in 2.5-Gy fractions). Although the PCI regimen was terminated during the study period because of the lack of definitive evidence of its efficacy, those who underwent PCI did not develop brain metastasis. Given that the main pattern of recurrence is distant, especially in the brain, further refinement of the multimodal treatment regimen is required to obtain better outcome.

Tumors in Proximity to the Carina

A tumor extending to within 2 cm of the carina is said to be a T3 tumor, and patients with this subset of tumors benefit from surgical resection in published series. Since the introduction of lung-sparing techniques by Price-Thomas¹² in 1947, sleeve lobectomy has been adopted by many thoracic surgeons,⁶⁵ and it is now the standard of procedure for NSCLC extending into the large airway whenever appropriate. The techniques can be applied to not only tumors in proximity to the carina but also those located at the origin of a lobar bronchus, those with positive margin after standard lobectomy, and those that are N1 disease and can be completely resected. Pneumonectomy or sleeve pneumonectomy should be strictly considered for lesions that cannot be completely removed by a lung-sparing procedure because of the higher postoperative morbidity and mortality. Deslauriers and colleagues²² reported a lower operative mortality in the sleeve lobectomy group compared with the pneumonectomy group (1.6% versus 5.3%). The authors reported the 5-year survival rates of 52% in the sleeve lobectomy group and 31% in the pneumonectomy group. The 5-year survival rates in the sleeve lobectomy group by nodal involvement were 63% in N0, 48% in N1, and 8% in N2. Although no series specifically reported on results of surgical resection of T3 tumors defined by proximity to the carina, negative mediastinal node disease and complete resection are keys for improved survival.^{22,66}

When a tumor involves not only the mainstem bronchus but also the proximal pulmonary artery, vascular sleeve resection is combined for complete resection. In the report by Yildizeli and coworkers⁶⁶ of 218 patients with sleeve lobectomy, 28 patients (13%) underwent vascular sleeve resection and most of them (20/28) were associated with left upper lobectomy. A meta-analysis reported by Ma and associates²³ suggested that sleeve lobectomy with or without vascular reconstruction can be performed without increasing mortality or morbidity compared with pneumonectomy, and it offers better survival than pneumonectomy.

Tumors Invading the Mediastinum or Diaphragm

The outcome in patients with mediastinal pleural involvement is generally poor because of frequent mediastinal node involvement. Riquet and colleagues⁶⁷ documented that 25 out of 68 patients (36%) with mediastinal pleural invasion who underwent surgical resection had N2

disease. The 5-year survival rate was reported as 31% in the study. Pitz and associates⁶⁸ documented a 5-year survival rate of 25% in patients with complete resection.

NSCLC invading the diaphragm is a rare condition and infrequently diagnosed preoperatively. Yokoi and coworkers⁶⁹ noted only one third of these patients (17 of 63 patients) had a diagnosis of diaphragmatic invasion before surgery, and Riquet and colleagues⁷⁰ reported only 3 out of 68 patients (4%) had the diagnosis preoperatively. Prognostic factors reported in this subset were nodal disease, completeness of resection, and the depth of diaphragmatic invasion. In the series of Yokoi and coworkers, 5-year survival rates by nodal disease were 28% (N0) versus 18% (N1/2), and those by the depth of diaphragmatic invasion were 33% (parietal pleura) versus 14% (diaphragmatic muscle or deeper). Rocco and colleagues⁷¹ reported the 5-year survival rate of 27% in patients with N0 disease and diaphragmatic invasion. The relatively poor prognosis of mediastinal or diaphragmatic involvement even in patients with N0 disease after complete resection can be explained by the extensive lymphatic and venous drainage,^{67,70} so adjuvant or neoadjuvant therapy should probably be offered for these subsets of patients.

Additional Nodules in the Primary Lobe

It is recognized that patients with pulmonary metastasis in a primary lobe have better survival than those with contralateral pulmonary metastasis or with other metastatic disease. In addition, it is often not possible to determine preoperatively whether a satellite nodule seen on a CT scan is a metastatic lesion or an inflammatory lesion, so satellite lesions in a primary lobe still warrant surgical resection. In recent surgical series, the 5-year survival rates in patients with pathologically proven pulmonary metastasis in a primary lobe have been reported to be from 45% to 57%.⁷²⁻⁷⁵ The node status is a significant prognostic factor in this subset of patients who underwent complete surgical resection, but whether the number of satellite lesions is a prognostic factor has yet to be clarified.

T Category: T4

The T4 category includes tumors directly invading important mediastinal structures such as the heart, esophagus, great vessels, trachea, vertebral body, or carina (see Table 17-1). Tumors with a malignant pleural effusion are reclassified into the M1 category, because the prognosis of this subset of patients is comparable with that of those with metastatic disease. The median survival of patients with malignant pleural dissemination is only 8 months, and the 5-year survival rate is 2%.³⁴ On the other hand, M1 based on additional nodules in the ipsilateral lung (different lobe) is reclassified as T4.

Generally, T4 tumors are deemed unresectable; however, curative surgical resection can be performed in highly selected patients with surgery alone or with a combined multimodality approach including chemotherapy, radiotherapy, or both. Patients with T4 tumors with mediastinal node disease (N2) are generally excluded

from being surgical candidates, because their prognosis is in general not improved. Therefore, every effort should be made to exclude N2 disease if surgical resection is considered. Furthermore, it is recommended by the American College of Chest Physicians' practice guideline that resection be undertaken only at an experienced, highly specialized center.⁷⁶

Heart and Great Vessels

Patients with T4 tumors by virtue of invasion to the heart are rarely candidates for surgical treatment. On occasion, central tumors extending around the inferior pulmonary vein and the left atrium may be amenable to complete surgical resection.⁷⁷ The tumor resection can be achieved by clamping the left atrium and then suturing the defect, or by removing tumors with the patient on cardiopulmonary bypass, if indicated (e.g., for cardiac chamber invasion with main pulmonary artery involvement).^{77,78} Tsuchiya and coworkers⁷⁹ reported a 5-year survival after left atrium resection of 22% in 44 patients with NSCLC. Riquet et al reported a surgical series of lung cancers invading to pericardium alone ($n = 32$), pericardium and pulmonary vein ($n = 34$), and pericardium and atrium ($n = 34$).⁸⁰ The mode of lung resection was predominantly pneumonectomy (>90%) in all three subsets. In the group with pericardium invasion, R0 resection was achieved in 81.3% of cases, but only 52.9% of cases in the group with pericardium and pulmonary vein invasion and 40% in the group with pericardium and atrium invasion. In the three subsets, the 5-year survival rates were 15.2%, 19.1%, and 7.2%, respectively.

Surgical resection of NSCLC involving great vessels, including the aorta, the main pulmonary artery, and the superior vena cava, can be performed either primarily or as a part of multimodality treatment. In patients with tumors invading the thoracic aorta or the subclavian artery, the surgical procedure varies from intra-adventitial dissection or direct lateral clamping and suturing with or without a patch, to replacement of a portion of artery with a prosthetic graft.^{81,82} These aggressive surgical resections are further justified when tumors extend into the arterial wall, because they carry a risk of sudden rupture or embolism. Several reports of superior vena cava resections for NSCLC have depicted survival rates according to the degree of primary tumor or nodal involvement. In general, a poor prognosis is seen in patients with mediastinal node disease (5-year survival, 52% in N0-1 versus 21% in N2),⁸³ those with superior vena cava invasion by metastatic lymph nodes (5-year survival, 36% in superior vena cava tumor invasion versus 6.6% in superior vena cava lymph nodal invasion),⁸⁴ or those with pneumonectomy (hazard ratio = 2.9 compared with lobectomy).⁸⁵ Induction treatment should be considered, because it may allow less pulmonary resection (i.e., lobectomy or sleeve lobectomy) by reducing tumor burden, and it may also decrease the distant failure rate.^{85,86}

Carina and Trachea

Carinal resection has been performed for patients with NSCLC invading the carina or extending to the lower

part of the trachea since the 1950s as a potentially curative treatment.⁸⁷ As a result of improvements in surgical techniques, perioperative management, and patient selection, the surgery-related hospital mortality continues to decrease. In the past decade, acceptable mortality rates in patients who underwent carinal pneumonectomy have been reported from several experienced institutions, ranging from 4% to 15%.⁸⁸⁻⁹³

As a part of mediastinal staging, some prefer to perform mediastinoscopy at the time of planned thoracotomy to avoid the development of scar tissue along the trachea, to help in reducing anastomotic tension by allowing good tracheal mobilization.^{88,90} Others perform mediastinoscopy preoperatively for possible induction chemoradiotherapy if pathologic N2 disease is confirmed.^{89,91} Recent advancement of EBUS-FNA may take the role of mediastinoscopy in the setting.⁹² A rigid bronchoscopy can be used to better assess the involved tracheobronchial tree, to determine resectability, and to plan airway reconstruction.

Various tracheobronchial anastomoses after carinal resection have been described by Mitchell and associates,⁹⁴ who reviewed the surgical experience at Massachusetts General Hospital. The techniques are described in [Chapter 8](#). A right carinal pneumonectomy is generally performed via right posterolateral thoracotomy, or occasionally bilateral thoracotomy, or sometimes median sternotomy is performed for bilateral reconstruction of the tracheobronchial tree. The approach for a left carinal pneumonectomy varies: median sternotomy, clamshell incision, left thoracotomy, or bilateral thoracotomy is used.

Mediastinal lymph node involvement is a strong prognostic factor.^{88-93,95} Whether adjuvant or neoadjuvant, or chemotherapy or chemoradiotherapy, should be used for those with N2 disease in this subset is still under debate. Recent series of carinal resection are summarized in [Table 17-3](#).

Ipsilateral Pulmonary Metastasis in Nonprimary Lobes

A recent report of a surgical series by Nagai and colleagues⁹⁶ demonstrated 5-year survival rates of patients with nonprimary lobe lung metastases of 42.1% (p-N0, $n = 38$), 7.9% (p-N1, $n = 19$), and 10.0% (p-N2, $n = 52$). In the study, approximately 60% of these patients received R0 (complete) resection, and 11% of cases received pneumonectomy. Significant survival differences were detected between node-negative (N0) and node-positive (N1 or N2) groups. Because the stage of the mediastinal node disease is a key prognostic factor, careful preoperative mediastinal investigation is necessary if surgical resection is to be considered in this subset of patients.

Vertebral Body

Patients with vertebral body involvement historically have been deemed unresectable; however, advances in surgical techniques, postoperative care, and induction chemoradiotherapy allow aggressive complete resection with an acceptable mortality for patients with vertebral

TABLE 17-3 Recent Series of Carinal Resection in Non–Small Cell Lung Cancer

body invasion.^{97,98} Several groups have reported outcomes of vertebral body resection (either total or hemi) in patients with NSCLC invading the spine. Grunenwald and associates⁹⁷ reported a 53% 2-year survival rate in 19 patients treated with vertebral body resection. Gandhi and coworkers⁹⁹ primarily performed surgery followed by radiotherapy in this subset and achieved a 2-year survival rate of 54%. Fadel and colleagues¹⁰⁰ documented a 3-year survival rate of 39%. Anraku and colleagues¹⁰¹ reported a 3-year survival rate of 58% in patients ($n = 23$) with T4 (vertebral body) N0 disease who underwent surgery including multiple total vertebrectomy (Fig. 17-6A). In the study, all patients received preoperative chemotherapy or chemoradiotherapy, and 45% of them achieved complete response to the neoadjuvant therapy by pathologic examination. R0 resection rate was high: 19 out of 23 patients (83%) achieved complete resection. The outcome in patients who demonstrated pathologic complete response or near-complete response (viable cells <1% in the resected specimen) was excellent, whereas the outcome in those who did not was poor (3-year survival, 93% versus 20%; see Fig. 17-6B). Because the high rates of both R0 resection and pathologic complete response were associated with better survival, a multimodality treatment approach with induction chemoradiotherapy should be strongly considered in carefully selected patients. Recent series of vertebral body resection are summarized in Table 17-4.

Esophagus

NSCLC invading the esophagus is rarely amenable to complete resection and the outcomes have been disappointing, so the presence of frank invasion to the esophagus is considered unresectable. Pitz and associates¹⁰² reported that only 3 out of 12 patients (25%) achieved complete resection in this subset of patients. The 5-year survival rate of resected NSCLC invading to the esophagus reported by Bernard et al was only 12%.¹⁰³

N Category: N0 and N1

Decision making in the treatment of patients with stage I/II (N0 or N1) NSCLC is relatively straightforward. Surgical resection (in most cases, lobectomy) is the mainstay of therapy if patients have good cardiopulmonary reserve. However, there is a growing body of evidence on types of surgical resection and combined neoadjuvant and

adjuvant therapy in the management of stage I/II disease. Therefore, accurate hilar/interlobar nodal staging is required. Preoperative EBUS-guided aspiration cytology of the N1 nodes (hilar and interlobar) may be useful in differentiating N0 and N1 disease to consider induction treatment before surgical resection as described by Yasufuku et al.¹⁰⁴ In clinical (CT- and PET-based noninvasive staging) N0 patients, the authors were able to confirm N0 disease in 87 (53.4%), upstaged 1 (0.6%) to N1 disease, and 6 (3.7%) to N2 disease.

In patients with clinical N0-1 disease, the type of pulmonary resection is dependent on T category and intraoperative assessment of nodal disease. As described (see “Sublobar Resection versus Lobectomy,” earlier), lesser resection such as segmentectomy would be an option for small-size peripheral NSCLC (T1 disease) if no nodal disease is confirmed intraoperatively. Therefore, intraoperative interlobar or hilar nodal assessment (or both) is critical in decision making for sublobar resection. VATS has been widely accepted for resection in this category. On the other hand, for patients with N0 NSCLC with local tumor invasion (T3 disease), an extended en bloc resection such as pneumonectomy, sleeve resection, chest wall resection, or other procedures can be performed to obtain cancer-free margins. Mediastinal lymph node sampling is essential for accurate cancer staging. The controversy as to whether complete MLND is included is discussed later in this chapter.

Cisplatin-based adjuvant chemotherapy has been shown to improve survival in patients with N1 and even in pathologic N0 disease, with completely resected, T1b or higher NSCLC based on phase III randomized clinical trials.^{105–107} Various combinations of chemotherapeutic agents; new nonplatinum agents, including molecular targeted drugs; and techniques of tumor molecular profiling are under investigation in efforts to further improve outcomes in patients with NSCLC.

N Category: N2

The option of offering surgery to patients with N2 disease (ipsilateral mediastinal or subcarinal node involvement) has been long debated. N2 disease comprises heterogeneous groups of patients, from those with micrometastatic mediastinal node involvement found intraoperatively (on frozen section) or postoperatively (on final pathologic examination) to those with bulky mediastinal node involvement recognized by the pre-treatment staging workup. In a study by Andre and coworkers,¹⁰⁸ patients with N2 disease proven before surgery (either by CT or mediastinoscopy) had significantly worse survival than those who did not have a diagnosis of N2 disease before surgery (Fig. 17-7). Patients with N2 disease are subjected to a combined treatment strategy including chemotherapy, radiotherapy, and surgery, but it remains controversial as to which of these treatment modalities should be included or in what sequence (i.e., before or after surgery). Albain et al conducted a randomized phase III study of 396 patients with stage IIIa NSCLC.⁷ In the study, patients with no progression after chemoradiotherapy were randomly assigned to either surgery or definitive radiotherapy. There was no significant difference in overall 5-year survival following surgery versus definitive radiotherapy (27% versus 20%; $P = 0.24$). However, improved progression-free and overall 5-year survivals of patients with lobectomy in the surgery arm were observed when compared to those of the radiotherapy arm (22 and 36% versus 11% and 18%; Fig. 17-8).

In the context of decision making in the treatment of N2 disease, there are two distinct scenarios according to when the nodal disease is definitely confirmed: (1) N2 disease confirmed by the pretreatment staging workup, and (2) N2 disease found at thoracotomy or at postsurgical pathologic examination (unexpected N2 disease).

FIGURE 17-7 ■ Survival of patients with N2 disease treated with primary surgery according to N2 status and number of levels involved. *cN2*, N2 disease proven by CT (lymph node > 1 cm in short-axis diameter) or mediastinoscopy before surgical resection; *mN2*, N2 disease not proven before surgery (all lymph nodes < 1 cm in short-axis diameter by CT or negative mediastinoscopy); *L1*, a single lymph node level involved; *L2+*, multiple lymph node levels involved. (From Andre F, Grunewald D, Pignon JP, et al: Survival of patients with resected N2 non-small cell lung cancer. *J Clin Oncol* 18:2981–2989, 2000.)

N2 Found on Pretreatment Staging

Patients with multistation, bulky (involved lymph nodes > 2 cm in short-axis diameter measured by CT scan), histologically or cytologically proven N2 disease are generally treated with nonsurgical modalities (i.e., chemotherapy or chemoradiotherapy), because complete resection would not be expected. On the other hand, those with nonbulky, multistation or single-station N2 disease found at staging, but without any sign of distant metastasis, are still potential candidates for curative surgical resection.^{7,109} Theoretical advantages of neoadjuvant treatment include (1) downsizing of the primary and nodal disease that may facilitate complete clearance of the nodal disease, (2) decreased chance of surgical seeding of tumor cells, (3) in vivo chemosensitivity or radiosensitivity checking of the tumor, and (4) better patient compliance with the treatment.¹¹⁰ Uy and colleagues¹¹¹ reported an improved overall median survival of 40 months in patients with biopsy-proven N2 NSCLC treated with induction chemoradiation followed by surgery, and in this patient population, pathologic response to induction treatment was also prognostic. However, the decision to proceed with surgical resection requires careful assessment after induction treatment including restaging, performance status, and pulmonary function tests. Especially for poor-risk patients who respond to induction chemotherapy, definitive radiotherapy is an option for treatment, as a recent randomized clinical trial conducted by the

FIGURE 17-8 ■ Survival after induction chemoradiotherapy followed by surgical resection (lobectomy or pneumonectomy) versus chemotherapy plus definitive radiotherapy in patients with stage IIIA (T1-3 pN2) non-small cell lung cancer. **A**, Lobectomy versus a matched cohort of chemoradiotherapy. **B**, Pneumonectomy versus chemoradiotherapy. *CT/RT*, Chemotherapy plus radiotherapy; *CT/RT/S*, chemotherapy plus radiotherapy followed by surgery. (From Albain KS, Swann RS, Rusch VW, et al: Radiotherapy plus chemotherapy with or without surgical resection for stage III non-small-cell lung cancer: a phase III randomised controlled trial. *Lancet* 374:379–386, 2009.)

European Organisation for Research and Treatment of Cancer (EORTC) Lung Cancer Group demonstrated comparable outcomes in the radiotherapy arm and the surgery arm.¹¹²

Mediastinal restaging and assessment after neoadjuvant treatment is of great importance, because residual N2 disease after chemotherapy appears to be an unfavorable prognostic factor, and surgical resection for these patients remains controversial. Although clinical restaging with chest CT is suboptimal for predicting pathologic response of metastatic lymph nodes to induction chemotherapy, integrated PET and CT^{113,114} and endobronchial ultrasound with transbronchial needle aspiration (EBUS-TBNA)^{92,104} have been used and may be promising in this

context. In a prospective study by Cerfolio and colleagues¹¹⁴ in patients with biopsy-proven N2 disease treated with induction chemoradiotherapy, PET plus CT was more accurate than CT alone for restaging. In their study, a greater than 50% decrease in the maximum standardized uptake value (SUV_{max}) in the metastatic lymph nodes was highly suggestive of pathologic clearance of cancer. Repeat mediastinoscopy after induction chemotherapy has been reported as useful with high sensitivity by Marra and colleagues.¹¹⁵ However, because it is an invasive procedure and known to be technically demanding, it is not regularly performed in clinical practice.

In a phase II study of induction chemotherapy followed by surgery in patients with mediastinoscopy-proven N2 disease, reported by Garrido and coworkers,¹⁰⁹ the 5-year survival was 17.6% in patients with residual pN1-3 disease (Fig. 17-9). In their study, patients downstaged to pN0 had significantly better survival (5-year survival, 51.6%) than those with pN1-3 disease. However, persistent minor mediastinal disease after induction chemotherapy may not always exclude surgical resection; in other words, some of those may be cured by surgical clearance of residual mediastinal disease. Doms and colleagues¹¹⁶ tried to select this subset of patients by means of serial ¹⁸F-fluoro-2-deoxyglucose (FDG)-PET scans taken before and after induction therapy. The authors demonstrated significantly better survival in patients with persistent minor mediastinal disease and a more than 60% decrease in the SUV_{max} than in patients with persistent minor disease but with a less than 60% decrease in SUV_{max} .

FIGURE 17-9 ■ Median survival according to pathologic downstaging in patients with mediastinoscopy-proof N2 with induction chemotherapy followed by surgery. (From Garrido P, González-Larriba JL, Insa A, et al: Long-term survival associated with complete resection after induction chemotherapy in stage IIIA [N2] and IIIB [T4N0-1] non small-cell lung cancer patients: the Spanish Lung Cancer Group Trial 9901. *J Clin Oncol* 25:4736-4742, 2007.)

N2 Found at Thoracotomy

The optimal management in patients with N2 disease found at thoracotomy (unsuspected N2 disease) is controversial. Treatment options include aborting lung resection followed by induction therapy and possibly followed by surgical resection, or proceeding with lung resection followed by adjuvant therapy. The rationale for the former decision is based on the favorable outcome of induction therapy followed by surgery obtained from published evidence including randomized clinical trials.¹¹⁷ In this era of VATS lung resection, however, it is reasonable to stop lung resection for induction therapy if N2 disease is discovered at the time of a VATS lobectomy, in which case the morbidity of the incision is small. On the other hand, with open thoracotomy, one may favor the latter option because the patient has already been exposed to the risks of general anesthetic and thoracotomy. In addition, patients who underwent thoracotomy (even without lung resection) may not be as compliant as those who undergo induction therapy before surgery. Cerfolio and colleagues¹¹⁸ reported a 5-year survival of 35% in patients who have completely resected unsuspected N2 disease after PET plus CT and thin-slice CT assessments (most likely reflecting minimal disease N2 status).

Controlling distant relapse is critical in patients with resected N2 NSCLC, because presence of N2 disease is known to be an indicator for high risk of metastatic relapse. Pisters and Le Chevalier¹¹⁹ summarized similar relapse rates in operable stage IIIA (N2) NSCLC (Table 17-5).

On this background, the use of adjuvant chemotherapy or radiotherapy has been extensively studied in resected N2 NSCLC, and adjuvant cisplatin-based chemotherapy appears to be beneficial, as proven by two recent randomized clinical trials. The Adjuvant Navelbine International Trialist Association (ANITA) trial demonstrated a reduced risk for death (hazard ratio, 0.69), with prolonged survival in patients who received adjuvant chemotherapy with or without radiotherapy compared with those without adjuvant therapy after complete surgical resection (Table 17-6).¹⁰⁶ A hazard ratio of 0.79 was reported in the International Adjuvant Lung

TABLE 17-5 Expected Outcome after Surgical Resection in Operable Non-Small Cell Lung Cancer

Cancer Trial (IALT), in favor of adjuvant chemotherapy compared with observation alone.¹⁰⁷

A past meta-analysis showed that postoperative mediastinal radiotherapy for patients with resected NSCLC has not been proven to be effective.¹²⁰ However, a more recent meta-analysis using the Surveillance, Epidemiology, and End Results (SEER) database of postoperative radiotherapy demonstrated prolonged survival in patients with stage IIIA (N2) disease.¹²¹ Results from the ANITA trial (nonrandomized subanalysis) also showed a benefit with postoperative radiation (see Table 17-6).

N Category: N3

Contralateral mediastinal lymph node metastases are considered a contraindication for surgery because long-term outcome with surgery has been dismal. The Southwest Oncology Group¹²² reported a 0% 3-year survival rate of patients with N3 NSCLC who underwent induction chemotherapy and radiotherapy followed by surgery. Because N3 lymph nodes are outside the surgical field and considered to be extensive lymphatic spread of cancer, complete surgical resection cannot be achieved. Therefore, we believe that patients with N3 disease should be treated nonsurgically.

M Category: M1a

M1a includes separate tumor nodules in a contralateral lobe, tumor with pleural nodules, and tumor with malignant pleural effusion.

Additional Nodules in the Contralateral Lung

Additional nodules in the *contralateral lung* are designated as M1a (previously M1), whereas those in the *primary lobe* are designated as T3, and those in the *ipsilateral lung (different lobe)* as T4, according to the seventh edition of the *TNM Classification for Lung Cancer*.³³ Based on the IASLC data, the median survival of patients with M1a disease was 10 months, with a 5-year survival rate of 3%,¹²³ which was significantly worse than that of same-lobe nodules or ipsilateral lung nodules (5-year survival, 28% and 21%, respectively). The median survivals of this subset of patients in the IASLC database and the SEER database

were 6 and 7 months, respectively. Therefore, additional nodules in the contralateral lung generally preclude surgery, although surgery may be offered for the primary NSCLC if the contralateral pulmonary lesions are questionable and mediastinal staging is negative. FDG-PET has appeared to be sensitive for detecting malignant metastatic disease,¹²⁴ but pathologic confirmation should be made by a percutaneous transthoracic needle biopsy or an excisional biopsy of those identified by PET, especially in the case of a solitary lesion.¹²⁵

When tumors represent double primaries (synchronous primaries) without mediastinal disease, the optimal treatment is two-staged lobectomy for contralateral tumors if the patient's lung function permits. When the cardiopulmonary reserve is limited, a lobectomy could be performed for the more advanced tumor and a limited resection (segmentectomy or wedge resection) for the contralateral tumor. Limited resection is in general reserved for smaller tumors or squamous carcinomas, because they are less likely to spread via the local lymphatic system, although this concept needs further study. Alternatively, bilateral segmentectomies can be considered for patients with very limited pulmonary function. A recent pooled analysis (N = 467) of completely resected synchronous NSCLC in multiple lobes revealed that advanced age, male gender, nodal involvement, and unilateral tumor location are poor prognostic factors.^{125a} In those who completed all their resections within a 6-month period (N = 412), median survival was 50.7 months.

A subtype of adenocarcinoma of the lung, adenocarcinoma in situ (AIS), is characterized as being multicentric and is frequently identified in its early stage with the advent of high-resolution CT. AIS can also exist with other types of NSCLC. The management of multifocal AIS or AIS with other non-small cell types is discussed later (see "Multifocal Adenocarcinoma In Situ").

Malignant Pleural Effusion

A histologically documented malignant pleural effusion is a contraindication for surgery because it is not amenable to complete resection. However, Ichinose and coworkers¹²⁶ reported a 5-year survival rate of 23% in surgical patients with a minimal amount of malignant pleural effusions (average, 37 mL) found at thoracotomy.

Long-term survivals (>5 years) have also been reported by Yokoi and colleagues¹²⁷ in highly selected patients with carcinomatous pleuritis without N2 disease who underwent extrapleural pneumonectomy.

M Category: M1b

Category M1b includes all distant metastasis outside the lung. The vast majority of lung cancer patients with distant metastasis are not curable by surgical treatment, and surgery is therefore precluded. However, there is some evidence for a potential role for surgical resection in patients with NSCLC who have an isolated distant metastasis in the adrenal gland or brain.

Adrenal Gland

A solitary adrenal metastasis in patients with otherwise operable NSCLC is a rare condition (incidence, 1.6%), because adrenal metastases are usually accompanied by other metastatic disease.¹²⁸ Based on reported series of adrenalectomy for isolated adrenal metastases in NSCLC, complete surgical resection of both the primary tumor and adrenal metastasis may improve survival in selected cases. Mercier and associates¹²⁹ reported a 5-year survival rate of 23% in 23 patients with NSCLC who underwent complete resection of an adrenal metastasis after surgical treatment of lung cancer. In the study, 6 patients presented with an adrenal metastasis found on the preoperative workup, and the remaining 17 patients were found to have an isolated adrenal metastasis during follow-up after lung resection. The complete adrenalectomy necessitated combined kidney ($n = 2$), inferior vena cava ($n = 1$), or liver ($n = 1$) resection. In the case series by Pfannschmidt and coworkers,¹³⁰ the median survival after adrenalectomy was 12.6 months ($n = 11$). Tanvetyanon and colleagues¹³¹ analyzed the pooled data from 114 cases in 10 publications describing outcomes of adrenalectomy in NSCLC. The authors concluded that the time between diagnosis of primary lung cancer and the discovery of adrenal metastasis (disease-free interval [DFI]) was prognostic. Patients with a DFI of 6 months or less demonstrated significantly shorter median survival than those with a DFI greater than 6 months (12 versus 31 months). An evidence-based clinical practice guideline published by the American College of Chest Physicians (ACCP) recommends curative resection of the primary N0-1 lung tumor and the isolated adrenal metastasis for those who are medically fit.¹³² The impact of adjuvant chemotherapy or radiation to the adrenal bed on long-term outcome remains undefined because of the scarcity of this population subset; however, the treatment strategy should be refined further because this subset may be detected more frequently as a result of improvements in diagnostics, including CT, magnetic resonance imaging, and PET.¹³³

Brain

NSCLC is known for its propensity to metastasize to the brain, and the form of dissemination is often multiple. It has been reported that 30% to 50% of patients with NSCLC are found to develop brain metastasis during the

course of their disease.¹³⁴ A solitary brain metastasis from lung cancer can be categorized into three subsets: (1) a synchronous primary lung cancer with a single brain metastasis, (2) a solitary brain metastasis found after successful treatment of the primary tumors, and (3) a single brain metastasis from an uncontrolled primary lung cancer. Here we will discuss only the first presentation of the brain metastases, because thoracic surgical oncologists may encounter such cases and be involved in the decision-making process. Thoracic surgeons should be aware, when they advise new surgical colleagues, that resection of a solitary brain metastasis in a patient with completely resected NSCLC carries a potential cure rate.

In a retrospective report from the Mayo Clinic by Billing and coworkers,¹³⁵ 28 out of 220 patients underwent surgical treatment of brain metastases from NSCLC. These patients were treated with surgical resection of synchronous brain metastases and the primary lung cancer. In this series, all craniotomies were performed before the primary lung cancer resections, with a median time between craniotomy and thoracotomy of 14 days. The most responsible factor influencing survival after surgery was the presence of thoracic lymph node metastases. The overall 5-year survival rate was 21.4%, but no patient with lymph node metastases (N1 and N2) survived longer than 3 years.

The advent of stereotactic radiosurgery (SRS) has offered another treatment option for patients with a solitary brain metastasis. Hu and coworkers¹³⁴ reported on outcomes of NSCLC patients with a solitary brain metastasis treated with either SRS or neurosurgery, in conjunction with chemotherapy, radiotherapy, or both, for the lung primary site. The median survivals for patients who had received treatment for their primary cancers and those who had not were 15.5 and 5.9 months, respectively. In addition, the survival times were thoracic stage dependent: median survivals by thoracic stage (I, II, and III) were 25.6, 9.5, and 9.9 months, respectively. The ACCP guideline summarized that the favorable prognostic factors in patients with isolated brain metastasis were young female gender, metachronous presentation, good performance status, or lower T stage.¹³² In the guideline, one can consider curative surgical approach for both the brain metastasis and the primary tumor if complete resection is likely to be achieved. Surgical resection or SRS, with or without whole brain radiation therapy to a solitary brain lesion, is the treatment of choice. Based on the reported series and the aforementioned guideline, patients with thoracic stage I NSCLC with a solitary brain metastasis appear to benefit from aggressive treatment including surgical resection of the primary site. Those with N2 disease should be excluded because the cancer involvement of mediastinal nodes portends a worse prognosis.

SPECIAL CONSIDERATIONS

Mediastinal Lymph Node Dissection versus Systematic Sampling

Tumor staging is critical for predicting prognosis, for comparing clinical studies, and, most importantly, for

planning therapy in lung cancer. To obtain more accurate mediastinal lymph node staging, intraoperative lymph node examination is necessary in early-stage (I and II) or selected stage III resectable disease. However, current practice varies from simple visual inspection of the mediastinum to radical MLND without having solid consensus among thoracic surgeons. In fact, it was reported that nodes were sampled at any mediastinal level during surgery in only 42% of patients with lung cancer in the United States.¹³⁶ The points of current debate with regard to surgical mediastinal staging, in particular, in comparing MLND with systematic sampling (SS) include safety, staging accuracy, and local control and long-term survival.

Operative Morbidity

The argument against MLND is that it might be associated with higher morbidity compared with SS. It can be assumed that chylothorax, phrenic or recurrent laryngeal nerve injury, increased lymphatic drainage/bleeding, or decreased host defense may occur because of resection of whole lymphatic drainage pathways and lymphatic tissues along with the local blood supply. However, recent reports, including a randomized clinical trial, demonstrated that MLND does not increase operative morbidity.¹³⁷⁻¹³⁹ Allen and colleagues¹³⁹ reported a large multi-institutional randomized trial (the American College of Surgeons Oncology Group trial, ACOSOG Z0030), in which patients with lung cancer were randomized to either lymph node sampling ($n = 498$) or lymph node dissection ($n = 525$). Operative mortality was 2.0% for the sampling group and 0.76% for the dissection group. Morbidity including minor complications was 38% in each group. Specifically, there were no statistical differences in the rates of chylothoraces, postoperative hemorrhage, recurrent nerve injuries, or BPFs. No statistical difference was observed in the duration of chest tube drainage (sampling versus dissection, 4 versus 5 days), median total chest tube drainage (1.34 versus 1.46 L), or the length of hospitalization (6 days in both groups).

Staging Accuracy

One of the critical questions is whether SS is as accurate as MLND in surgical mediastinal staging. If mediastinal lymph node assessment is not adequately performed, the true N stage remains unrecognized, which may result in false downstaging. In the ACOSOG Z0030 trial, all patients first received lymph node sampling with frozen section examination. When all required lymph nodes biopsied were negative for malignancy on frozen section, then those patients were randomized to either sampling only, with no further dissection, or to complete MLND. Positive mediastinal nodes were found in 20 patients (3.8%) who had negative sampling and were randomized to MLND. Therefore, these patients would have unrecognized N2 disease without the dissection.

In the nonrandomized trial reported by Keller and colleagues,¹³⁷ SS was as efficacious as MLND in accurate nodal staging, with rates of detected N2 disease of 60%

in the SS group ($n = 112/187$) and 59% in the MLND group ($n = 110/186$). However, MLND detected significantly more levels of N2 disease (multiple N2 levels: 30% in MLND versus 12% in SS) in the study. The result is comparable to prospective randomized trials reported by Izbicki and associates (17.4% in SS versus 57.2% in MLND)¹⁴⁰ and by Wu and colleagues (28% in SS versus 48% in MLND).¹⁴¹

One might ask whether complete MLND is always necessary for patients with early-stage, small-size NSCLC, as such cases are frequently and increasingly identified today. In a prospective randomized trial for patients with clinical T1N0 NSCLC less than 2 cm in diameter ($n = 115$), Sugi and coworkers¹⁴² found no statistical differences in N2 detection rates (13% in both groups) or in survival rates between the groups and thus concluded that SS is adequate.

A unique multicenter cross-sectional study was performed by Massard and associates¹⁴³ to answer the question of whether MLND elevates diagnostic accuracy. The authors performed lymph node sampling first, followed by complete MLND in each patient enrolled in the study ($N = 208$). The sampled nodes and the nodes from MLND were examined separately, so each case served as its own control. Of 60 patients with pathologic N2 disease, lymph node sampling identified only 31 patients (52%) as having N2 disease. Furthermore, multilevel N2 disease was detected by sampling in 10 out of 25 patients (40%). The authors concluded that lymph node sampling is inadequate in determining accurate N stage.

Local Control and Long-Term Survival

A postulated argument is that MLND contributes not only to improved staging but also to tumor control and long-term prognosis; however, the therapeutic efficacy of MLND remains under debate. If SS fails to identify positive mediastinal nodes, it may result in an increased risk of local recurrence in comparison with MLND. On the other hand, it might be hypothesized that MLND may help in clearing occult micrometastatic cells in the mediastinal lymph nodes that are not identified by conventional histopathologic methods¹⁴⁴ and thus may increase the rate of complete resection. The latter hypothesis is supported by the fact that local tumor recurrence is significantly higher in patients with pathologic stage I or pathologic N0-1 disease who underwent SS than in those who underwent MLND (45% versus 13%, and 46% versus 13%, respectively).¹³⁸

A few prospective randomized studies have examined these issues. A study by Izbicki and colleagues¹⁴⁵ demonstrated that MLND appeared to prolong the relapse-free interval compared with SS in patients with pathologic N1-2 disease; however, there was no significant difference in survival. Sugi and associates¹⁴² conducted a prospective randomized study of SS and MLND in patients with clinically diagnosed peripheral NSCLC less than 2 cm in diameter. The patients were assigned to a lobectomy with SS ($n = 56$) or a lobectomy with MLND ($n = 59$). In the study, no significant differences were found in recurrence rate or survival between the groups. On the other hand, a more recent prospective randomized trial

conducted by Wu and coworkers¹⁴¹ demonstrated a survival benefit of MLND over SS (median survival, 59 versus 34 months) with a reduced local recurrence rate (2.9% versus 4.8%). The difference in survival was prominent in stage I (5-year survival, 82.2% versus 57.5%) and stage IIIA (27.0% versus 6.2%). Recent evidence from the literature relating to the potential benefit of MLND on both local control and long-term outcome are summarized in Table 17-7.

The large, prospective, randomized multicenter trial of MLND ($N = 525$) versus SS ($N = 498$) during pulmonary resection in patients with early-stage NSCLC (N0 or nonhilar N1, T1, or T2) (ACOSOG Z0030) demonstrated no significant difference in local, regional, or distant recurrence between the two groups.¹⁴⁶ Furthermore, MLND did not improve survival if thorough pre-resection sampling of the mediastinal and hilar lymph node was negative for cancer metastasis. The median survival rates were 8.1 years for SS and 8.5 years for MLND, and the 5-year survival rates were 69% and 68%, respectively.

Multifocal Adenocarcinomas In Situ or Minimally Invasive Adenocarcinomas

The terms *bronchioloalveolar carcinoma* and *mixed subtype adenocarcinoma* (WHO 1999 and 2004 definitions) have been discontinued in the 2011 International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society (IASLC/ATS/ERS) lung adenocarcinoma classification.^{146a} New classifications have been introduced, such as *adenocarcinoma in situ* (AIS) and *minimally invasive adenocarcinoma* (MIA) for small solitary adenocarcinomas with pure lepidic growth and predominant lepidic growth with 5 mm or greater invasion, respectively.

AIS and MIA are known for their multifocal nature, including bilateral lung involvement, although the cause

of the multifocality is under debate.¹⁴⁷ One radiographic appearance of AIS, known as ground-glass nodule (GGN), is characterized as a localized, mild-to-moderate increase in density on a CT scan without obscuring preexisting bronchovascular structures. A focal GGN can contain solid parts in the lesion that often represent invasive components. High-resolution CT is useful for correlating the radiographic appearance of GGN with pathologic features, including mediastinal node involvement.^{148,149}

Treatment Strategy and Outcome

A single lesion of AIS or MIA can be cured surgically by standard lobectomy with lymph node dissection. Asamura et al reported excellent surgical results of clinical stage IA patients with radiographically determined noninvasive lung adenocarcinoma who underwent lobectomy with MLND.¹⁵⁰ Specifically, if the ratio of maximum diameter of consolidation (C) divided by the maximum tumor diameter (T) (the C/T ratio) on high-resolution CT images was less than 0.5, the 5-year survival was 96.7%.

Given its multifocal process and better outcome compared with other non-small cell types, attempts have been made with complete surgical resection for multifocal AIS and/or MIA, or for those with other non-small cell types. Clinically, invasive lung adenocarcinomas can present with synchronous, multifocal, AIS or MIA lesions that appear as pure or near-pure GGNs. The optimal approach in this circumstance remains unclear. Gu et al took a strategy of anatomic pulmonary resection of a dominant, invasive lesion and wedge resection of accessible ipsilateral GGNs.¹⁵¹ On the other hand, Kim et al reported the long-term outcome of multifocal pure GGNs found in patients who had surgical resection for bronchioloalveolar carcinoma (BAC).¹⁵² In the latter study, 18 patients had some of the ground-glass lesions resected and the remaining lesions followed by serial CT scans with a median follow-up of 40.3 months. The

TABLE 17-7 Impact of Mediastinal Lymph Node Dissection (MLND) or Systematic Sampling (SS) on Local Recurrence and Long-Term Outcome in Patients with Resectable Non-Small Cell Lung Cancer

Author (Year)	Study Design (N of Patients)	Clinical Stage	MLND vs. SS	
			Local Recurrence (%)	Disease-Free Median Survival (mo, but % when 5-yr)
Izbicki et al ¹⁴⁵ (1998)	Randomized (169)	I-III	28.9 vs. 34.4 (NS)	48 vs. 24 (NS)
Sugi et al ¹⁴² (1998)	Randomized (115)	I	10 vs. 13 (NS)*	81.4% vs. 83.9% (overall 5-yr, NS)
Keller et al ¹³⁷ (2000)	Nonrandomized (373)	II, IIIA	52 vs. 58 (NS)*	57.5% vs. 29.2 [†]
Wu et al ¹⁴¹ (2002)	Randomized (471)	I-IIIA	2.9 vs. 4.8	59 vs. 34 [†] p-St. I, 82.2% vs. 57.5% [†] (5-yr) p-St. II, 50.4% vs. 34.1% (5-yr, NS) p-St. IIIA, 27.0% vs. 6.2% [†] (5-yr)
Lardinois et al ¹³⁸ (2005)	Nonrandomized (100)	I, II	p-St. I, 13 vs. 45 [†] p-St. II, 17 vs. 55 (NS) p-St. IIIA, 23 vs. 10 (NS)	p-St. I, 60.2 vs. 44.8 [†] p-N0, 52.8 vs. 44.8 [†] All, 46.2 vs. 41.1 (NS)

[†]Distant recurrence included.

NS, Not significant; p-St., pathologic stage.

ground-glass lesions either did not change in size ($n = 15$) or they disappeared ($n = 3$). The authors concluded that a close follow-up with CT scan can be an alternative if resection(s) of pure GGNs is not feasible. Mun and colleagues¹⁵³ reported clinicopathologic results of thorascopic resections for patients with small, peripheral, multifocal BAC (105 BAC lesions in 27 patients). In the study, the surgeons performed lobectomies or lesser resections (segmentectomy or wedge resection) with or without lymph node dissection. All lesions demonstrated GGN with no solid components (pure GGN) on the preoperative high-resolution CT scan. There was no local recurrence observed; however, interestingly, de novo BAC lesions developed in 26% of the patients after the surgical treatment.

In summary, sublobar resection may be offered for solitary, small, peripheral ground-glass lesions with no radiographic sign of invasive growth, whereas standard lobectomy should be performed for those with invasive growth features radiographically. Complete surgical resection appears to be a preferable option for multifocal GGNs if mediastinal nodes are not involved, because these cases should not be considered as T4 or M1a disease.

SURGICAL TREATMENT OF SMALL CELL LUNG CANCER

Small cell lung cancer (SCLC) represents 15% of all lung cancer in North America¹⁵⁴ and is characterized by rapid growth and early dissemination. Only approximately 30% of the patients with SCLC have limited disease (LD). LD-SCLC is treated with curative intent with chemoradiotherapy with median survival of 23 months and a 5-year survival rate of 12% to 17%, whereas extensive-disease SCLC is treated primarily with chemotherapy with a median survival of approximately 7 to 12 months, and the proportion surviving 5 years is only 2%.¹⁵⁴

The treatment for patients with lung cancer including SCLC was primarily surgery before 1970, but surgery was largely discouraged after a report from the Medical Research Council in the United Kingdom.¹⁵⁵ This trial showed a small but significant difference in the survival rate—a 4-year survival of 3% in the surgery arm versus 7% in the radiotherapy arm. Because all patients who survived 5 years were treated in the radiotherapy arm, this became the standard form of treatment for LD-SCLC. The role of surgery as initial treatment was reevaluated after introduction of the TNM staging system. Shields and colleagues¹⁵⁶ reported the experience of the Veterans Administration Surgical Oncology Group (VASOG) and concluded that surgical resection is indicated in patients with T1N0 SCLC. At approximately the same time, the reduction of local recurrence of LD-SCLC by surgical resection was emphasized by the Toronto group.¹⁵⁷ These findings revived interest in the role of surgery in the treatment of early-stage SCLC. Furthermore, the role of adjuvant chemotherapy after surgical resection was investigated by several groups,¹⁵⁸⁻¹⁶⁰ which enhanced the benefit on improved survival. In 1983, the Lung Cancer

Study Group initiated a prospective randomized trial in which patients treated with induction chemotherapy were randomized to undergo surgical resection or to receive radiotherapy.¹⁶¹ Although several criticisms can be made, this is the only prospective randomized trial for LD-SCLC comparing surgery with radiotherapy to date. Median survival was 15.4 months in the surgery arm ($n = 70$) and 18.6 months in the radiation arm ($n = 76$). The authors concluded that surgical resection did not contribute to either prolonged survival or local control. Conclusions are limited by the fact that in the surgical arm, only 77% ($n = 54$) of patients underwent complete resection. Also, neither platinum-based chemotherapy nor concurrent chemoradiotherapy was used, and the modern preoperative neoadjuvant therapy might be more potent. Finally, patients with peripheral nodules, assumed to be T1N0, who might be the best candidates for surgery, were specifically excluded from this study.

Rationale for Surgery

Evolving from a number of case-series reports and prospective phase II trials, the role of surgery in LD-SCLC has been shaped by several rationales: (1) Small peripheral lesions without any nodal involvement can occasionally be misdiagnosed as SCLC when they are in fact typical or atypical carcinoid tumors. (2) Surgical resection for LD-SCLC (T1N0, T2N0) may improve local control compared with chemoradiotherapy. (3) Mixed-histology tumors (a SCLC tumor with an NSCLC component) may not be completely eradicated by chemoradiotherapy because the NSCLC component is less sensitive to chemotherapy. (4) Salvage surgery for chemoresistant localized SCLC or local relapse after an initial response to chemotherapy or chemoradiotherapy may be more effective than current second-line chemotherapy. A final indication for surgery is a second primary tumor with NSCLC histology after cure of initial SCLC. Although only a small percentage of patients with SCLC survive longer than 2 years, the occurrence of a second primary NSCLC is becoming more common with current advances in the treatment of SCLC. It is worth noting that any new tumor arising more than 2 years after initial treatment for SCLC is in fact more likely to be of non-small cell histology. Patients without mediastinal node metastases can be treated with surgery. However, survival is reduced in patients with a stage I second NSCLC who underwent wedge resection compared with patients with primary stage I NSCLC receiving wedge resection (median survival, 24.5 versus 58.4 months).¹⁶²

Improved Local Control

Although the mainstay of the current treatment for LD-SCLC is chemotherapy with or without radiotherapy, even the current active chemoradiotherapy protocols have demonstrated local failure rates of 36% and 52%.¹⁶³ The first site of recurrence in patients with LD-SCLC who achieve complete remission is the primary tumor site, followed by hilar or mediastinal lymph nodes.¹⁶⁴ In an autopsy series, only 31% of patients who underwent surgery had residual primary tumor, whereas 92% of

patients with LD-SCLC who had negative mediastinoscopy but were treated without surgery had residual disease at the primary site. Shepherd and colleagues¹⁵⁷ reported on the Toronto experience, with a combined treatment program including surgical resection, and demonstrated local relapse in only 2 of 35 patients. A recent report from a German group has demonstrated 100% local or locoregional control after complete surgical resection following induction chemoradiotherapy for LD-SCLC, with a 5-year survival rate of 63%.¹⁶⁵ There are no available data from randomized control trials comparing modern chemoradiotherapy protocols with chemoradiotherapy with surgery; however, the impact of surgical resection on local control seems to be evident. In this context, surgical treatment for SCLC appearing as a solitary pulmonary nodule without nodal involvement would be a justifiable strategy. Particularly if the diagnosis is uncertain or in question, surgery can be an initial step in the management of T1-2 N0 SCLC. In a recent Japanese trial, the 5-year survival rates in patients with clinical stage IA (T1N0) and IB (T2N0) postoperatively proven SCLC who underwent complete resection followed by chemotherapy were an encouraging 73% and 67%, respectively.¹⁶⁶

Mixed-Histology Tumors

According to the World Health Organization classification of lung carcinoma (1999), the variants of SCLC admixed with various other histologic types are defined as combined small cell carcinoma. Recent surgical series of neuroendocrine lung tumors revealed that 26.6% of resected SCLC fell into this category.¹⁶⁷ In studies of induction chemotherapy followed by adjuvant surgery for pathologically confirmed SCLC, an NSCLC component was found in the resected specimen in 11% to 15% of cases.^{161,168} The high percentage of combined SCLC in surgical reports is partially because combined SCLC tends to be in the periphery rather than in the hilum and thus surgical resection may be more feasible. In addition, because of the large amount of tissue available in surgical cases (i.e., the entire tumor), the chance of finding other components may increase. Another possible reason is that, because the NSCLC component is less sensitive to chemotherapy than the SCLC component, residual tumors, which are more likely to be surgically treated, may be more likely to contain an NSCLC component. Therefore, it is reasonable to offer surgical resection to improve local control if a histologic diagnosis of mixed SCLC without nodal involvement is obtained. It must be part of a combined modality approach, because surgery alone is not adequate for the SCLC component. An NSCLC component may be responsible for local relapse or the poor response to chemoradiotherapy, so surgery may be offered as salvage treatment.

Surgery as a Salvage Treatment

Because the treatment of relapsed or unresponsive LD-SCLC with second-line chemotherapy is generally unsatisfactory, salvage surgery for these cases offers another treatment option. The Toronto group has

identified a small but curable subset of patients who benefit from salvage surgery.¹⁶⁹ In this prospective study, the authors offered surgery for patients with residual disease after chemotherapy, radiotherapy, or both, or with local failure after the initial response to chemotherapy. After resection, 10 of 28 patients were found to have a mixed histology or pure-NSCLC tumor, although 25 of 28 patients were thought to have a pure-SCLC tumor preoperatively. The 10 patients with mixed histology or pure-NSCLC tumor achieved a median survival of more than 2 years. In contrast, patients with pure-SCLC tumors rarely survived more than 2 years. Therefore, patients with mixed histology in their residual or nonresponsive tumor without nodal disease may be good candidates for salvage surgery. In this view, it is worth considering a second biopsy to reevaluate the cell type.

TNM Staging (Seventh Edition) and Surgical Outcome

The revised TNM staging is now applied not only to NSCLC but to SCLC based on the recent analysis of the SCLC cases in the IASLC database.¹⁷⁰ Applying pathologic TNM staging to the data of 349 cases of resected SCLC clearly separated patient subgroups with different prognoses (Fig. 17-10). Overall 5-year survival rates of resected stages IA and IB were 56% and 57%, respectively. Even in the groups of stages IIA and IIB, 38% and 40% 5-year survival rates were obtained. The results support the use of surgical resection as a part of the multimodal treatment for SCLC. Subsequent analysis of the SEER database, the 5-year survival rate of patients with stage I SCLC who underwent lobectomy without radiotherapy was 50.3%.¹⁷¹ Another recent analysis of the English National Cancer Repository (NCDR) showed that the 5-year survival rate of SCLC undergoing surgical resection was 31% despite its inherent poor prognosis.¹⁷² In summary, surgery is indeed a viable option for the treatment of LD-SCLC. How best to integrate it into multimodal treatment programs and how to improve patient selection for surgery are key considerations for further refinement of the treatment strategy in these patients.

SUMMARY

Surgical resection in patients with NSCLC continues to be the mainstay of curative treatment, and the techniques continue to evolve. VATS and, more recently, robot-assisted surgery allow thoracic surgeons to perform minimally invasive surgery on early-stage tumors without violating key oncologic principles. On the other hand, improvements in surgical techniques, intraoperative management, and postoperative care allow more radical resections of tumors invading other organs. Neoadjuvant, adjuvant, or both therapies should be considered in the treatment for most patients with resectable NSCLC (excluding stage IA) if medically fit. Accurate tumor staging continues to be the key to determining optimal treatment strategy.

SUMMARY

The surgical approach in the management of patients with lung cancer continues to evolve and improve. Conventional surgical approaches (including standard posterolateral thoracotomy, muscle-sparing thoracotomy, trans-sternal thoracotomy, and median sternotomy) remain viable options for some patients with resectable lung cancer. However, minimally invasive procedures have increasingly gained acceptance as a standard surgical modality for early-stage lung cancer, with increasing application to more advanced disease, as a means of minimizing operative morbidity without sacrificing oncologic efficacy.

DEFINITION

Minimally invasive procedures, using operative telescopes and video technology, are referred to synonymously as thoracoscopic procedures or video-assisted thoracic surgery (VATS). For clarity, the terms *VATS* and *thoracoscopic* refer to totally thoracoscopic approaches, where rib spreading is avoided and visualization depends on video monitors.¹ A hybrid procedure, which employs rib spreading and direct visualization in addition to thoracoscopy, may be referred to as *video-assisted thoracotomy*. Thoracoscopy has been widely used diagnostically in the management of patients with lung cancer; thoracoscopic

wedge resection to confirm malignancy prior to thoracotomy for anatomic resection is commonly performed. In addition, thoracoscopic therapeutic procedures, including pleurodesis for malignant pleural effusion and pericardial window for pericardial effusions, are also frequently performed. The application of thoracoscopic anatomic resections is no longer new and is increasingly used internationally. In the most recent analysis of the Society of Thoracic Surgeons (STS) General Thoracic Surgery Database, thoracoscopic lobectomy constituted 45% of all lobectomies performed.²

Thoracoscopic lobectomy is defined as the anatomic resection of an entire lobe of the lung, using a videoscope and an access incision (<8 cm), without the use of a mechanical retractor and without rib spreading.¹ The anatomic resection includes individual dissection and stapling of the involved pulmonary vein, pulmonary artery, and bronchus and appropriate management of the mediastinal lymph nodes, as would be performed with thoracotomy. In selected patients, thoracoscopic anatomic segmentectomy may be performed, adhering to the same oncologic principles that guide resection at thoracotomy.³ Theoretical advantages to minimally invasive resection include reduced surgical trauma and inflammation, decreased postoperative pain, shorter chest tube duration, shorter length of stay, preserved pulmonary function, and numerous short-term and long-term outcomes.⁴⁻⁹

BRIEF HISTORY

The history of minimally invasive thoracic surgery began in 1910 when Jacobaeus used a cystoscope to lyse adhesions to collapse the lung to treat tuberculosis.¹⁰ This technique was widely applied in the early part of the century but was largely abandoned after streptomycin was introduced in 1945. However, with the emergence of laparoscopic cholecystectomy, minimally invasive approaches were applied more widely. The first descriptions of the use of VATS for anatomic lobectomy were published in 1993 by Walker and colleagues.¹¹ The first large single institution series, published in 2006,^{12,13} supported the safety and feasibility demonstrated in the Cancer and Leukemia Group B multi-institutional, prospective study.¹

INDICATIONS

In general, the indications for thoracoscopic lobectomy are similar to those for lobectomy using the open approach.^{1,12-15} Thus, the procedure is applied to patients with known or suspected lung cancer (clinical stage I-II) if the disease appears amenable to complete resection by lobectomy. Preoperative staging and patient selection for thoracoscopic lobectomy should be conducted as for conventional thoracotomy.¹⁶ With increasing focus on operative planning and experience with the VATS techniques, the indications for thoracoscopic lobectomy are evolving. Whereas initially a history of prior surgery, the presence of an endobronchial lesion, or even the administration of induction chemotherapy were once regarded as contraindications, the experience that has since been gained, together with improvements in instrumentation and thoracoscopic imaging, have now changed this situation in most hospitals with experience in VATS. As such, recent studies have shown that lobectomy by VATS in cases of lung cancer with prior chemotherapy can be carried out safely and effectively, without an increase in the rate of complications.¹⁷ And although endobronchial lesions were previously considered a contraindication to VATS resections, bronchoplastic procedures and pneumonectomy are now commonly performed minimally invasively.^{15,18}

Tumor size may preclude the option of thoracoscopic lobectomy in some patients, as some large specimens (tumors greater than 6 to 8 cm in diameter) may not be amenable to removal without rib spreading, possibly negating the benefit of minimal access surgery. However, no absolute size criteria have been applied. Although it is controversial, some have argued that the thoracoscopic approach may allow recruitment and resection of some patients considered medically inoperable, who could not undergo conventional thoracotomy.^{1,14,19,20} A study by Cattaneo and colleagues²¹ demonstrated improved tolerance of thoracoscopic lobectomy as compared with thoracotomy lobectomy in patients older than 70 years of age. Several studies have further demonstrated that VATS lobectomy is beneficial in reducing pulmonary complications in patients with poor preoperative pulmonary function.^{2,22} The minimal physiologic requirements for

resection have not been agreed on; however, the selection of patients for thoracoscopic lobectomy must take into account that conversion to thoracotomy may be necessary.

CONTRAINDICATIONS

Absolute contraindications to thoracoscopic lobectomy include the inability to achieve complete resection with lobectomy, T3 (chest wall) or T4 (local invasion) tumors, active N2 or N3 disease, and inability to achieve single-lung ventilation.^{14,15} Relative contraindications include tumors visualized in the lobar orifice at bronchoscopy (although successful thoracoscopic sleeve resection has been reported),¹⁸ the presence of complex, calcified benign hilar lymphadenopathy that would complicate vascular dissection, and prior thoracic irradiation. Prior thoracic surgery; T3 tumors that involve the pericardium, mediastinal pleura, or diaphragm; incomplete or absent fissures; and benign noncalcified mediastinal adenopathy should not be considered contraindications.^{15,23} Increasing experience has allowed successful thoracoscopic lobectomy after induction therapy, including for patients with stage IIIA (N2) disease.¹⁷ Finally, chest wall involvement would obviate thoracoscopic resection for most patients, but successful hybrid thoracoscopic lobectomy with en bloc chest wall resection has been demonstrated to be safe and feasible.²⁴

The efficacy of mediastinal lymph node dissection (MLND) has been questioned.²⁵ Several studies have examined the extent of MLND by VATS versus open lobectomy. In one study by Kondo and coworkers,²⁶ thoracotomy was performed for reassessment of lymph nodes following MLND using VATS and yielded few additional lymph nodes (mean = 1.3 lymph nodes, median 0 lymph nodes). Similarly, Sugi et al²⁷ found no difference between the number of lymph nodes dissected among patients who underwent VATS (mean = 8.4 ± 1.0) versus patients who had open lobectomy (mean = 8.2 ± 1.5). More recently, a retrospective review by Watanabe and colleagues²⁸ of 770 patients with cN0-pN2 non-small cell lung cancer who underwent VATS ($n = 450$) or open lobectomy ($n = 320$) examined the total number of lymph nodes, number of lymph node stations, and number of mediastinal nodes and mediastinal stations by VATS versus open lobectomy, and found no difference in any of these categories. Data from the recent American College of Surgeons Oncology Group Z0030 trial ($N = 752$, VATS = 66, open = 686) has also confirmed the efficacy of MLND during VATS procedures by demonstrating a similar number of lymph nodes removed and lymph node stations assessed as compared with thoracotomy.²⁹

Other studies comparing the efficacy of a lymph node dissection of a VATS lobectomy with standard thoracotomy have demonstrated similar results.^{30,31} Nevertheless, it remains that some surgeons doubt the efficacy of VATS MLND. To date, few studies have disputed the efficacy of MLND by VATS, with one study by Denlinger and colleagues³² ($n = 79$ VATS, $n = 464$ open) showing fewer lymph nodes sampled by VATS compared

with thoracotomy (7.4 ± 0.6 versus 8.9 ± 0.2 , $P = 0.03$) and fewer N2 nodes (2.5 ± 3.0 versus 3.7 ± 3.0 , $P = 0.004$). In a recent study by D'Amico et al³³ analyzing data from the National Comprehensive Cancer Network database with a more balanced number of VATS versus open procedures ($N = 388$, $n = 199$ VATS, $n = 189$ open), VATS and thoracotomy were found to result in a similar number of mediastinal lymph nodes resected (median = 4 for both groups) and N2 nodes resected (median = 3 for both groups). The percentage of patients with at least three mediastinal lymph node stations assessed, as recommended by the current guidelines, was also similar in the VATS and open group (66% VATS versus 58% open, $P = 0.12$).

STRATEGY FOR THORACOSCOPIC LOBECTOMY

After bronchoscopy and mediastinoscopy (when indicated), single-lung anesthesia is established using a dual-lumen endotracheal tube or bronchial blocker. The patient is positioned in a full lateral decubitus position with slight flexion of the table at the level of the hip, which provides splaying of the ribs to improve thoracoscopic access and exposure. Care must be taken to secure and pad the patient so that the risk of neurologic injury is minimized. Once the patient is positioned, the anesthesiologist should reconfirm the desired position of the endotracheal tube. Before sterile preparation and draping, the chest is marked for the placement of thoracoscopic incisions.

Port placement is a matter of surgeon preference. Most surgeons use three or four incisions, although lobectomy can usually be accomplished using only two incisions.¹⁵ Using this strategy, the first incision, either a 5-mm or 10-mm port access used predominantly for the thoracoscope, is placed in the seventh or eighth intercostal space in the mid-axillary line. The location of this incision is chosen so that it does not compete with the anterior incision, yet it still provides anterior and superior visualization of the hilum. A port is used for placement of the thoracoscope, but ports are not used for the other incisions. Before making the second incision, evidence that the patient is unresectable, such as parietal pleural involvement, should be sought.

The second incision, an anterior access incision (usually 4.5, but up to 6.0 cm) for dissection and specimen retrieval, is placed in the fifth or sixth intercostal space, just inferior to the breast. The location of this incision, where the intercostal spaces are the widest, is chosen to provide access for hilar dissection and is usually not dependent on whether the planned procedure is an upper or lower lobectomy. A wound protector may be used in the access incision to improve soft tissue retraction, to facilitate suctioning, and to protect the incision during specimen removal. Additional incisions may be used, either in the axilla or posteriorly, to improve visualization or to provide retraction.

Instrumentation for thoracoscopic lobectomy is critical to successful completion of the procedure. The thoracoscope should be a 30-degree angled scope to optimize

the ability to achieve panoramic visualization during dissection and to minimize competition with the operative instruments. Alternatively, a 45-degree angled scope or a flexible scope may be used, although this may be more difficult for an assistant to navigate. A spectrum of surgical instruments may be used for dissection, including conventional instruments and dedicated thoracoscopic or laparoscopic instruments. It is especially beneficial to use curved instruments for retraction during dissection, as they minimize the tendency for instruments to compete or collide with each other. Thoracoscopic (linear) mechanical staplers, such as the Endo GIA (Covidien, Norwalk, CT), are employed for control of the vessels (2.0- or 2.5-mm staples), bronchus (3.5- or 4.8-mm staples), and fissure.

After placing the access incision, the surgeon performs thoracoscopic exploration, which includes confirming the location of the tumor, excluding the presence of pleural metastases, and dividing the pulmonary ligament for lower lobectomy. If a malignant diagnosis has not been achieved preoperatively, thoracoscopic wedge resection is performed using an automatic stapling device, and the specimen is removed, either in a protective bag or with a wound protector. After frozen section confirms a malignant diagnosis, thoracoscopic lobectomy may be completed. MLND may be performed at this point or may be deferred until the lobectomy is completed.²⁵

The approach to the staging of mediastinal lymph nodes is controversial. Many advocate systematic sampling of mediastinal lymph nodes because of concerns about the adequacy and safety of formal dissection.^{25,34} Others accomplish MLND by complete resection of the mediastinal nodes thoracoscopically, including levels 2, 4, 7, 8, and 9 on the right and levels 5, 6, 7, 8, and 9 on the left.²⁵ A minimum of three mediastinal stations should be assessed.^{16,33}

Hilar dissection is carried out through the access incision, to achieve visualization and mobilization of the hilar structures. When upper lobectomy is being performed, division of the posterior pleural reflection permits elongation of the hilum and facilitates further resection. For any anatomic thoracoscopic lobectomy, hilar dissection is begun with mobilization of the pulmonary vein, although alternative strategies may be employed depending on the size and location of the tumor. For upper lobectomy, the lung is reflected posteriorly and inferiorly to facilitate dissection. For lower lobectomy, the lung is retracted superiorly. Moving the thoracoscope to the anterior incision may improve visualization of the superior hilum and may facilitate placement of the linear stapler for upper lobectomy if it is introduced through the mid-axillary (camera) port.

The risk of intraoperative hemorrhage is minimized with careful hilar dissection, which is facilitated with the visual clarity and magnification available with the video thoracoscope. Unexpected bleeding from a major branch of the pulmonary artery or pulmonary vein may occur, however. In most cases, the source of the bleeding is easily identifiable and tamponade is possible, allowing conversion to thoracotomy. To minimize the risk of vascular injury, surgeons have employed various techniques to isolate the pulmonary arterial and venous branches,

including ligatures to retract the vessels, and catheters to guide the stapling devices. These techniques may be helpful in difficult cases but are not required for most patients.

All lobectomy specimens are removed using a protective specimen bag to prevent implantation of tumor cells in the incision. The lobectomy specimen and hilum are inspected to ascertain that anatomic lobectomy has been performed. After retrieval, the hemithorax is irrigated with warm saline and the bronchial stump is inspected. If an air leak is encountered, repeat stapling or endoscopic suturing may be performed.

SPECIFIC TECHNICAL CONSIDERATIONS

Left Upper Lobectomy

With the thoracoscope in the mid-axillary incision, the horizontal and oblique fissures are inspected and the presence of the tumor in the left upper lobe is confirmed. The lung is retracted posteriorly, and the superior pulmonary vein is identified and mobilized. The left superior pulmonary vein is then encircled using a curved clamp; dissection behind the superior pulmonary vein allows identification of the pulmonary artery (Fig. 18-1). The stapling device is then applied (Fig. 18-2), and the superior pulmonary vein is divided, exposing the pulmonary artery. The pulmonary artery is mobilized, focusing on the apical and anterior branches (Fig. 18-3), which may then be stapled and divided. The left upper lobe bronchus is now visualized and may be stapled and divided (Fig. 18-4). Subsequently, the branches of the posterior and lingular arteries are stapled (Fig. 18-5). Finally, the fissures are completed and the specimen is retrieved.

Right Upper Lobectomy

Right upper lobectomy is slightly more difficult than left upper lobectomy because both horizontal and oblique fissures must be managed. With the thoracoscope in the

FIGURE 18-2 ■ Left superior pulmonary vein, just prior to division with stapler.

FIGURE 18-3 ■ Apical anterior branches of the left pulmonary artery.

FIGURE 18-1 ■ Left superior pulmonary vein, encircled with a curved clamp.

FIGURE 18-4 ■ Left upper lobe bronchus, encircled with a curved clamp.

FIGURE 18-5 ■ Posterior and lingular branches of the left pulmonary artery.

mid-axillary incision, the horizontal and oblique fissures are inspected and the presence of the tumor in the right upper lobe is confirmed. After the completion of the division of the posterior pleural reflection, dissection of the bronchus and removal of the level 11 lymph nodes may be undertaken. At this point, stapling and division of the right upper lobe bronchus is often feasible, facilitating future arterial dissection.

The right lung is then retracted posteriorly, and the superior pulmonary vein is identified and mobilized to identify the division between the middle lobe and upper lobe venous branches. The upper lobe branches are encircled using a curved clamp; dissection behind the superior pulmonary vein allows identification of the pulmonary artery. The stapling device is then applied and the vein is divided, exposing the pulmonary artery. The pulmonary artery is mobilized, and the apical anterior trunk (truncus anterior) may then be stapled and divided. Subsequently, the posterior ascending arterial branch is stapled. The right bronchus is now exposed, and if not already managed, the upper lobe bronchus may be stapled and divided. Finally, the horizontal fissure (anteriorly) and the oblique fissure (posteriorly) are completed and the specimen is retrieved.

Right Middle Lobectomy

With the thoracoscope in the mid-axillary incision, the horizontal and oblique fissures are inspected and the presence of the tumor in the middle lobe is confirmed. The lung is retracted posteriorly, and the superior pulmonary vein is identified and mobilized to identify the division between the middle lobe and upper lobe venous branches. The middle lobe vein is encircled and stapled, exposing the middle lobe bronchus and artery. Retraction of the middle lobe laterally and posteriorly optimizes exposure of the bronchus. At this point, the bronchus is encircled and stapled, further exposing the middle lobe artery. The middle lobe artery is then stapled and divided as well, allowing completion of the fissures.

Lower Lobectomy (Right or Left)

The strategy for lower lobectomy is similar on the right and left sides. With the thoracoscope in the mid-axillary incision, the presence of the tumor in the lower lobe is confirmed. The lung is retracted anteriorly, and the pleura is incised between the lung and the esophagus. The lung is then retracted laterally and superiorly to incise the pleura overlying the inferior pulmonary vein, which can then be encircled and stapled after ascertaining that the superior segment branch is included in the dissection. Further superior retraction of the lower lobe improves exposure of the bronchus at the bifurcation of the lower lobe bronchus and the middle lobe bronchus (right lung) or lingular bronchus (left lung). The lower lobe bronchus is then encircled and stapled, exposing the lower lobe arterial trunk, which is then stapled and divided. Finally, the fissure is completed and the specimen retrieved.

Segmentectomy

Thoracoscopic segmentectomy is an option for anatomic resection in patients with poor lung function (forced expiratory volume in 1 second [FEV₁] or diffusion capacity less than 50% of predicted) or synchronous primary tumors. In addition, small (≤ 2 cm), peripheral primary tumors (particularly with minimally invasive histology), well-centered in the segment of interest, may be candidates.^{3,35-39} These resections may be successfully completed thoracoscopically.⁴⁰

The segments that are technically easiest to resect are the superior segments of the lower lobes, the lingular segment of the left upper lobe, the composite basilar segments of the lower lobes (sparing the superior segment), the upper division of the left upper lobe (sparing the lingua), and the posterior segment of the right upper lobe. A segmentectomy should not be performed when the tumor is immediately encroaching on the intersegmental fissure. The closest segmental margin should exceed 2.0 cm or the diameter of the tumor. The surgeon should always resect all intersegmental lymph nodes in addition to the hilar and mediastinal nodes that are routinely taken at the time of lobectomy.⁴⁰

Wedge Resection

Lobectomy is considered the procedure of choice in most patients with early-stage lung cancer, as it is associated with a lower rate of local recurrence and higher overall survival compared with sublobar resections.¹⁶ When sublobar resections are an option, anatomic segmentectomy is preferred. However, in patients with small peripheral tumors who will not tolerate anatomic resection or in whom anatomic resection would be extraordinarily difficult, wedge resection (sometimes followed by radiotherapy) may be the best surgical option.¹⁶ VATS wedge resections of small (<3 cm) peripheral nodules are usually carried out using endoscopic stapling devices to transect lung parenchyma. Larger and more centrally located nodules are more challenging.

RESULTS

The safety and efficacy of thoracoscopic lobectomy for patients with early-stage lung cancer have been established. Although there are no prospective, randomized series that compare thoracoscopic lobectomy with conventional approaches, a sufficient number of series have been published, including single-institution and multi-institution experiences, as well as meta-analyses, to conclude that thoracoscopic lobectomy is a reasonable strategy for patients with clinical stage I lung cancer.

The Cancer and Leukemia Group B (CALGB) reported on the results of a prospective, multi-institutional registry series of 127 patients who underwent thoracoscopic lobectomy.¹ In this series, the mortality was 2.7%, the operative time was 130 minutes, and the median length of stay was 3 days. Since that first multi-institutional study demonstrated the safety and feasibility of minimally invasive lobectomy, numerous subsequent studies have analyzed the potential advantages of this approach.

Postoperative Pain

One of the best studied advantages of thoracoscopic lobectomy is a reduction in postoperative pain.^{19,40,41,42} Nomori and colleagues⁴¹ compared a group of age- and sex-matched patients who underwent thoracoscopic lobectomy ($n = 33$) or limited anterior thoracotomy ($n = 33$). The patients who underwent thoracoscopic lobectomy experienced less pain between postoperative day (POD) 1 and POD 7 ($P < 0.05$ - 0.001) and had lower analgesic requirements up to POD 7 ($P < 0.001$). Demmy and Curtis¹⁹ reported on their results in a series of patients who underwent either thoracoscopic lobectomy or conventional thoracotomy. In this series, the percentage of patients reporting severe pain was 6% after thoracoscopic lobectomy and 65% after thoracotomy. Moreover, the percentage of patients reporting minimal or no pain was 63% after thoracoscopic lobectomy and 6% after thoracotomy.

Chronic discomfort is also an important issue in postoperative recovery. Although more difficult to measure than acute pain, chronic pain and shoulder dysfunction have been studied. Stammberger and colleagues,⁴³ in addressing long-term quality of life following VATS, reported that 53% of 173 patients undergoing VATS had insignificant pain 2 weeks after the operation. At 6 months, 75% had no complaints, and only 4% had mild or moderate discomfort at 2 years.

Postoperative Pulmonary Function

Many have theorized that smaller incisions and absence of rib spreading may improve lung function in the postoperative period, and several studies have reported pulmonary function test (PFT) data after thoracoscopic resection. Two studies examined postoperative arterial oxygen tension (PaO_2) after both VATS and muscle-sparing thoracotomy and found that VATS patients had better oxygenation during the first postoperative

week.^{44,45} Others have demonstrated improvements in early postoperative FEV_1 and forced vital capacity in the first weeks and months after VATS.^{8,19}

Systemic Inflammatory Effects

Minimally invasive procedures appear to produce less of a systemic insult than more conventional, invasive procedures.^{7,8,46-50} Many groups have studied inflammatory mediators after VATS and open resection and have found lower levels of C-reactive protein and interleukins (ILs) in those having undergone VATS.^{7,8,46} Yim and colleagues⁷ analyzed the cytokine responses in a series of 36 matched patients who underwent thoracoscopic lobectomy or conventional thoracotomy and lobectomy. Analgesic requirements were significantly lower in the patients who underwent VATS lobectomy. In addition, the levels of IL-6 and IL-8 were lower in the VATS group than in the group that underwent thoracotomy. Leaver and coworkers⁴⁶ examined immunosuppression due to systemic effects of surgery and found higher numbers of CD4 lymphocytes and natural killer cells and less suppression of lymphocyte oxidation in the VATS group. These studies have shown that VATS lobectomy leads to a reduced inflammatory response, less postoperative reduction in immunosuppression, and less impairment of cellular cytotoxicity than does open lobectomy. These findings could partially explain why perioperative outcomes of VATS lobectomy are superior to the perioperative outcomes of open lobectomy. Whether these trends toward more effective immune function after VATS resection lead to faster recovery or better long-term oncologic outcomes will be important endpoints of future studies.

Oncologic Effectiveness

The ultimate acceptance of thoracoscopic lobectomy will be dependent on its oncologic effectiveness as compared with conventional lobectomy. To date, only one small prospective, randomized trial has compared oncologic results of VATS with open lobectomy. In this study, published in 2000, Sugi and colleagues²⁷ reported that for 100 patients with stage IA non-small cell lung cancer undergoing either open ($n = 52$) or VATS ($n = 48$) lobectomy, there was no difference in 3- and 5-year survival rates. Although this trial is without sufficient power to assess differences between the operations, several additional retrospective studies performed are sufficient for limited analysis. First, most studies demonstrate no differences in number of lymph nodes obtained either by dissection or sampling between conventional and VATS lobectomy.^{25-31,33} Second, data from existing series reveal survival rates for patients with stage I disease that were at least as good as those published in the literature for conventional thoracotomy.³⁴ Some analyses have further documented improved survival when VATS was used.^{4,5} Reasons for the possible differences are unclear, but it has been postulated that preservation of immune function and less systemic release of inflammatory cytokines may be contributing factors.³⁴ In addition, the benefit of adjuvant treatment for resected stage II lung cancer necessitates attempts to maximize planned chemotherapy doses

postoperatively. Thoracoscopic lobectomy, with its lower morbidity rates, allows a high proportion of patients to receive all intended doses.^{51,52}

Cost-Effectiveness

The assessment of cost-effectiveness is controversial because of the difficulty in identifying and including all costs. It is clear that VATS can be associated with high costs of consumables and with longer operative times in inexperienced hands. However, numerous disposable instruments essential to performing thoracoscopic lobectomies, such as linear endoscopic staplers, are also used by many in performing either conventional or limited thoracotomies. Nakajima and colleagues⁵³ published a study from Japan demonstrating that hospital charges were actually lower for the VATS approach. One important variable in the assessment of cost-effectiveness is length of hospital stay. In most series of thoracoscopic lobectomy, the median length of stay was only 3 days.^{1-3,6,13,14} As surgeon experience increases with thoracoscopic lobectomy, the operative times will become comparable to those of conventional approaches. In fact, the mean operative time in the CALGB multi-institutional study was only 130 minutes.¹

A recent study by Swanson et al⁵⁴ used the Premier Perspective Database to compare hospital costs for VATS and open lobectomy procedures in the United States. A total of 3,961 patients underwent either open lobectomy ($n = 2907$) or VATS lobectomy ($n = 1054$). Hospital costs took into account costs associated with the operation, length of stay, and adverse events. Hospital costs were found to be significantly higher for open versus VATS lobectomy, though costs associated with VATS lobectomy were influenced by surgeon experience, whereas this was not the case with open lobectomy.

Overall Complications

The observation that thoracoscopic lobectomy may have a lower complication profile has been supported in multiple studies analyzing outcomes of series including patients undergoing thoracoscopic lobectomy and patients undergoing open lobectomy. In one study, 122 patients undergoing thoracoscopic lobectomy and 122 patients undergoing thoracotomy were compared.⁵⁵ Overall, the incidence of postoperative complications was lower in the thoracoscopic group (17.2% versus 27.9%, $P = 0.046$); however, these patients were matched for age and sex only, and there was no significant difference in the incidence of any of the specific complications reported. Whitson and colleagues⁵⁶ analyzed the outcomes of 147 (unmatched) patients who underwent lobectomy, including 88 by thoracotomy and 59 by thoracoscopy. Thoracoscopic lobectomy was associated with a lower incidence of pneumonia but with no difference in other complications, including blood loss, atrial fibrillation, or number of ventilator days.

Using a prospective database, the outcomes of patients who underwent lobectomy at Duke from 1999 to 2009 were analyzed with respect to postoperative complications.⁵⁷ Propensity-matched groups were analyzed, based on preoperative variables and stage. Of the 1079 patients

in the study, 697 underwent thoracoscopic lobectomy and 382 underwent lobectomy by thoracotomy. In the overall analysis, thoracoscopic lobectomy was associated with a lower incidence of prolonged air leak ($P = 0.0004$), atrial fibrillation ($P = 0.01$), atelectasis ($P = 0.0001$), transfusion ($P = 0.0001$), pneumonia ($P = 0.001$), sepsis ($P = 0.008$), renal failure ($P = 0.003$), and death ($P = 0.003$). In the propensity-matched analysis based on preoperative variables comparing 284 patients in each group, 196 patients (69%) who underwent thoracoscopic lobectomy had no complications versus 144 patients (51%) who underwent thoracotomy ($P = 0.0001$). In addition, thoracoscopic lobectomy was associated with fewer prolonged air leaks (13% versus 19%; $P = 0.05$), a lower incidence of atrial fibrillation (13% versus 21%; $P = 0.01$), less atelectasis (5% versus 12%; $P = 0.006$), fewer transfusions (4% versus 13%; $P = 0.002$), less pneumonia (5% versus 10%; $P = 0.05$), less renal failure (1.4% versus 5%; $P = 0.02$), shorter chest tube duration (median 3 versus 4 days; $P < 0.0001$) and shorter length of hospital stay (median 4 versus 5 days; $P < 0.0001$).³

Similar results were obtained when the STS database was analyzed by Paul and colleagues.⁶ All patients undergoing lobectomy as the primary procedure via thoracoscopy or thoracotomy were identified in the STS database from 2002 to 2007. After exclusions, 6323 patients were identified: 5042 underwent thoracotomy, 1281 underwent VATS. A propensity analysis was performed, incorporating preoperative variables, and the incidence of postoperative complications was compared. Matching based on propensity scores produced 1281 patients in each group for analysis of postoperative outcomes. After VATS lobectomy, 945 patients (73.8%) had no complications, compared with 847 patients (65.3%) who had lobectomy via thoracotomy ($P < 0.0001$). Compared to open lobectomy, VATS lobectomy was associated with a lower incidence of arrhythmias ($n = 93$ [7.3%] versus $n = 147$ [11.5%]; $P = 0.0004$), reintubation ($n = 18$ [1.4%] versus $n = 40$ [3.1%]; $P = 0.0046$), and blood transfusion ($n = 31$ [2.4%] versus $n = 60$ [4.7%]; $P = 0.0028$), as well as a shorter length of stay (4.0 versus 6.0 days; $P < 0.0001$) and shorter chest tube duration (3.0 versus 4.0 days; $P < 0.0001$). No difference was found in operative mortality between the two groups.⁴

Finally, two important meta-analyses assessed the advantages of the thoracoscopic approach. In the first, analyzing the outcomes of 21 studies comparing VATS and open approaches, Yan and colleagues⁴ demonstrated that there were no significant differences in locoregional recurrence but that VATS lobectomy was associated with a reduced systemic recurrence rate ($P = 0.03$) and improved 5-year mortality rate ($P = 0.04$). Cao and colleagues⁵ performed a similar analysis, focusing on studies that included propensity matching. In this meta-analysis, VATS was associated with a lower risk of perioperative morbidity ($P = 0.0004$), confirming the single and multiple institution series in the literature.^{6,58}

LOCALLY ADVANCED DISEASE

The results of patients who underwent lobectomy with chest wall resection were recently reviewed. Of 78

patients who underwent lobectomy and chest wall resection, 68 patients had resection via thoracotomy and 10 patients had a hybrid thoroscopic approach.²⁴ Preoperative, perioperative, and outcome variables were assessed using standard descriptive statistics. All patients underwent complete resection with negative margins. Patients who underwent the hybrid thoroscopic approach had shorter lengths of stay and fewer complications. Advantages of this approach include smaller incision size overall, precision of dissection, and avoidance of rib spreading and scapular retraction/rotation.

Nwogu and colleagues⁵⁹ studied the feasibility of VATS pneumonectomy. In their review of 70 patients who underwent pneumonectomy for malignancy from 2002 to 2008, 24 were done via a VATS approach and 35 via an open approach with 8 conversions to open procedures. In this series, 34% of patients had induction therapy, and these patients were proportionally distributed between the groups. Patients who underwent VATS had shorter lengths of stay and less blood loss. Patients who required conversion had significantly more operative blood loss. Complication rates were similar among all three groups.

Finally, it has been demonstrated that neither T status (>3 cm), nor N status ($>N0$), nor central location is a contraindication to thoroscopic lobectomy.⁵⁸ In a study of 1195 patients who underwent thoroscopic lobectomy, the results of patients with small, peripheral, and clinically node-negative tumors were compared with results of patients who had tumors larger than 3 cm, central tumors, or node-positive tumors. In this study, larger and more central tumors did not increase the complication rates or the conversion rates. While the conversion rate was higher in patients with N1 disease, the complication rate was similar in this subgroup as well.

SUMMARY

Minimally invasive approaches to lung cancer treatment have been demonstrated to be safe and effective for patients with early-stage lung cancer. Thoroscopic lobectomy is designed to achieve the same oncologic result as conventional lobectomy: complete hilar dissection and individual vessel control. The recognized advantages of thoroscopic anatomic resection include less short-term postoperative pain, shorter hospital stay, preserved pulmonary function, better compliance with adjuvant chemotherapy, and fewer complications. As techniques evolve, thoroscopic strategies are increasingly applied to locally advanced lung cancer as well. Although there are no sufficiently powered prospective randomized studies comparing the thoroscopic approach with conventional thoracotomy, there are no data from published series to suggest any difference in oncologic efficacy.

CHAPTER OUTLINE

ADJUVANT THERAPY

Adjuvant Chemotherapy

Adjuvant Radiotherapy

INDUCTION THERAPY

Induction Chemotherapy for Early-Stage
Non-Small Cell Lung Cancer

Induction Therapy for Stage IIIA/B Non-
Small Cell Lung Cancer

Induction Chemoradiotherapy

Special Circumstance: Superior Sulcus
Tumors

RECOMMENDATIONS

Although long regarded as the best chance for cure, surgery alone has significant shortcomings in the management of non-small cell lung cancer (NSCLC). Even in the most favorable of circumstances (stage I), failure of therapy is anticipated in 20% to 40% of patients.¹⁻³ Moreover, because most patients do not have localized disease at time of initial diagnosis, surgical resection is offered to only a minority of all patients with NSCLC.

Considerable effort has been directed toward developing preoperative (induction or neoadjuvant) and postoperative (adjuvant) strategies to improve long-term outcome after surgery and to increase the total number of resectable patients. These strategies use chemotherapy and radiation singly, sequentially, or concurrently.

Predicting which patients will not be cured by resection alone would clearly permit identification of appropriate candidates for multimodality treatment. To this end, locoregional lymph node involvement is a powerful predictor of cancer recurrence and should be thoroughly investigated during treatment planning.^{4,5} Tumor histology and size also affect cancer-related and overall survival of resected patients.⁶⁻⁸ Numerous genetic markers are being discovered that may further refine outcome prediction when combined with current imaging modalities (e.g., positron emission tomography).⁹⁻¹¹ Recent reports have proposed systems using histologic and molecular criteria to stratify predicted survival of resected patients.¹²⁻¹⁴

In developing strategies for combined therapies, patterns of failure must be considered. Locoregional recurrence after resection of stage I cancers is rare, but it is fairly common when regional lymph nodes are involved. The impact of improving local control with adjuvant radiotherapy may not translate to a survival advantage because patients seldom die from local recurrence. Even

in the presence of local lymph node involvement, completely resected patients with stage II cancers are still twice as likely to fail systemically as locally.¹⁵ Moreover, patients (stage IB-IIIa) who recur after resection with curative intent show distant sites of disease in up to 75% of cases.¹⁶ Consequently, effective adjuvant systemic therapy (chemotherapy) would be favored to adjuvant local therapy (radiotherapy) for resected cancers at high risk for recurrence.

ADJUVANT THERAPY

Despite enthusiasm for 35 years of promising clinical trials of multimodality treatment of NSCLC, it has only recently become apparent that there is a clear and consistent benefit of adjuvant therapy for resected lung cancer. This ambiguity may have been partly because chemotherapy and radiation protocols are changed frequently, resulting in large numbers of studies that cannot be compared. Also, few studies have been designed to critically examine treatment effects on specific NSCLC stages, as most studies tend to group stages I through III in their treatment arms. This shortcoming has been compounded by lack of accurate, sophisticated staging in most trials.

Unfortunately the promising results generated at high-volume academic centers do not, for a number of reasons, easily translate to less specialized, smaller institutions.^{17,18} Regardless, all patients with the diagnosis of NSCLC should be evaluated by a multidisciplinary team or physician adept in the care of patients with lung cancer in order to recommend and coordinate the optimal therapeutic approach.^{19,20} It is also essential that treated patients are carefully followed.

Adjuvant Chemotherapy

Early randomized trials of adjuvant chemotherapy focused on the use of nitrogen mustard,²¹ cyclophosphamide,²² and a combination of lomustine and hydroxyurea.²³ Cumulatively, these trials demonstrated that treated patients had more postoperative complications without survival benefit. In fact, patients treated with adjuvant cyclophosphamide experienced a worse long-term survival rate than untreated patients.²² This was independently confirmed by meta-analysis.²³ Findings from these early studies have since been discounted because histologic type and pathologic stage were not considered during trial design and chemotherapeutic agents used in these trials have since been demonstrated to be ineffective, if not detrimental, for patients with NSCLC.

As several studies began documenting the efficacy of platinum-based agents for advanced (stage IV) NSCLC, platinum-based adjuvant regimens were trialed with resected patients. Initial enthusiasm was generated when the Lung Cancer Study Group trial²⁴ suggested a disease-free and overall survival benefit in the adjuvant treatment arm. Although the survival advantage was not considered statistically significant, sufficient optimism was generated to continue investigations of platinum-based chemotherapeutic protocols. However, several subsequent trials continued to demonstrate minimal efficacy, even though continued trial design flaws were identified.

A randomized study of cyclophosphamide, doxorubicin, and cisplatin adjuvant therapy for resected stage I to II NSCLC²⁵ did not demonstrate treatment efficacy. This trial suffered from inability to deliver the prescribed chemotherapeutic regimen over the prescribed time and also the toxicity and limited usefulness of doxorubicin in the treatment of NSCLC. Less than 30% of patients in the treatment arm actually received chemotherapy as intended. Other randomized studies have been similarly plagued by incomplete delivery of prescribed postoperative therapies,^{26,27} which in part contributes to the negative findings. Additionally, the dose of cisplatin (40 to 60 mg/m²/cycle) used in most previous trials is substantially lower than currently recommended (80 to 120 mg/m²/cycle).²⁸

Although all of these early platinum trials were considered statistically negative, subtle survival differences were noted between control and treated patients in essentially every study. Not surprisingly, a 1995 meta-analysis of several randomized adjuvant platinum-based trials demonstrated a 13% reduction in the risk of death ($P = 0.08$) for treated patients.²⁹ This finding fueled continued interest in this platinum-based adjuvant treatment and spawned several modern trials. Platinum dosage was adjusted so that patients were scheduled to receive 300 to 400 mg/m² (total dose). Adjuvant radiation therapy was often left to the discretion of participating centers. Two such studies demonstrated trends favoring a survival benefit in treated patients, but neither was considered to be a positive trial.^{30,31} However, the International Adjuvant Lung Cancer Trial^{32,33} demonstrated a clear survival benefit of adjuvant platinum-based chemotherapy. This study included resected stage I to III patients and found a survival advantage, 5% benefit after 5 years ($P = 0.003$),

favoring the adjuvant chemotherapy arm versus surgery alone. This survival advantage is similar in magnitude to that achieved by adjuvant chemotherapy for resected breast and colon cancers.^{34,35}

The Lung Adjuvant Cisplatin Evaluation (LACE) pooled data from the five largest randomized trials at the time and reanalyzed this collective.³⁶ This study amassed information from more than 4500 patients and concluded that postoperative cisplatin-based chemotherapy significantly improves survival in patients with NSCLC. Trials contributing to LACE were heterogeneous with regard to stage (I to III), and subsequent subgroup analysis of pooled data provided insight into the differential effect of adjuvant therapy on specific stages of resected cancer. Based on results from LACE, there is little doubt that resected stage II and III patients experience a meaningful survival advantage from adjuvant chemotherapy—at least 5% for overall survival and 6% for disease-free survival.³⁶ Patients with resected stage IB disease, however, have much less benefit, although there is a trend toward some advantage in much the same way as in Cancer and Leukemia Group B (CALGB) 9633, a trial of adjuvant carboplatin and paclitaxel for resected stage IB patients only.³⁷ An important finding of CALGB 9633 was that patients with resected tumors larger than 4 cm do, indeed, benefit from adjuvant chemotherapy.³⁷ Current guidelines recommend that patients with stage IIA-B and IIIA (with occult N2 disease) receive a platinum-based postoperative chemotherapy regimen.^{19,20} Stage IA-B NSCLC patients who have been completely resected (R0) are advised not to receive postoperative chemotherapy at this time.¹⁹

The application of molecular inhibitors as adjuvant therapy in lung cancer is an area of intense current interest. However, a recent phase III adjuvant clinical trial of gefitinib, an epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor (TKI), versus placebo in resected NSCLC was closed early as interim analyses demonstrated either no benefit or potential detrimental impact.³⁸

Adjuvant Radiotherapy

Studies of the efficacy of adjuvant radiotherapy are confounded by many of the same factors that have plagued, and continue to plague, chemotherapy trials. Many randomized adjuvant radiotherapy trials are composed of patients from all stages of resected NSCLC. Consequently, the expected negligible (or deleterious) effects on patients with early-stage cancer may obscure small beneficial effects for patients with more advanced disease. Also, because the field of radiation oncology has evolved so quickly, many early randomized studies became obsolete before their data had matured. Moreover, most early randomized trials were underpowered. Consequently, it is not surprising that, although feasibility and retrospective studies often yield promising results, no randomized data exist to suggest a survival benefit of postoperative radiotherapy (PORT).

At this time, there is no justification to include adjuvant radiotherapy for resected stages I and II NSCLC. Three randomized trials,³⁹⁻⁴¹ as well as meta-analyses of trials (PORT studies),^{42,43} document a deleterious effect on survival of adjuvant radiotherapy for early-stage

NSCLC. Postulated reasons for this include poor radiotherapy planning,⁴¹ larger fraction sizes,³⁹ greater total radiation dosage,³⁹⁻⁴¹ outdated equipment, and poor quality control.⁴⁴

Although there was some optimism that hilar lymph node (N1)-positive patients (stage II) would provide a good substrate for adjuvant radiotherapy, this does not appear to be the case. Based on subgroup analysis of several randomized trials,^{42,43,45,46} radiotherapy has no significant effect on either local control or overall survival for these patients.

Finally, there are insufficient data to defend use of adjuvant radiotherapy for resected stage III (N2/N3) disease, as well. Even though improved local control has been reported,^{45,46} this has not translated into a meaningful survival benefit. The strongest argument to support adjuvant radiotherapy for resected stage III NSCLC comes from a nonrandomized, single-institution, retrospective study.⁴⁷ Investigators in this study found that PORT was the strongest independent predictor of survival for resected N2-positive disease. This study, however, has been widely criticized,⁴⁴ and PORT meta-analyses consistently fail to demonstrate efficacy for adjuvant radiotherapy for stage III disease.^{42,43} Yet, controversy remains over radiotherapy used in this setting, as one recent trial of adjuvant chemotherapy demonstrated improved 5-year overall survival when patients received thoracic radiation (after their chemotherapy) for resected stage III disease.⁴⁸

INDUCTION THERAPY

Induction or neoadjuvant therapy is any systemic or regional cytoreductive treatment (e.g., chemotherapy, radiotherapy, chemoradiotherapy) administered before definitive locoregional therapy (e.g., surgery). Aggressive surgical (mediastinoscopy or video-assisted thoracoscopic surgery [VATS]) or interventional (transbronchial needle aspiration or endoscopic ultrasound-guided fine-needle aspiration) staging is imperative to ensure that induction therapy protocols are applied to homogeneous patient populations. Some patients may be rendered inoperable because of grade 3 or 4 induction therapy toxicities, and this must be considered and discussed with patients during treatment planning.

Use of chemotherapy in the induction setting has several potential advantages. First, there is earlier initiation of treatment for possible micrometastatic (systemic) disease. Because distant recurrence is the most common mode of failure,¹⁶ early eradication of systemic disease might translate into a survival advantage, and chemotherapy is most effective when the tumor burden is small.⁴⁹ Also, drug delivery and cytotoxic effects may be enhanced as a result of preservation of mediastinal (and possibly tumor) blood supply. Perhaps most important, however, is that a higher percentage of patients will receive their intended dose of chemotherapy when drugs are delivered preoperatively.^{50,51} Neoadjuvant therapy also allows for a period of smoking cessation before resection, a critical element in improving NSCLC patient outcomes.^{52,53}

Induction radiotherapy in combination with chemotherapy has and continues to be investigated vigorously. Two large phase III trials comparing only induction radiotherapy (40 to 50 Gy) were reported several decades ago.^{54,55} Both demonstrated inferior survival rates for irradiated patients. Since then, limited data have emerged to suggest a role for radiotherapy alone as an induction modality. Consequently, induction radiotherapy is discussed primarily in the context of chemoradiotherapy protocols.

Wide adoption of induction therapy is not without concern. Subsequent resections are generally more technically challenging and may result in lung-sparing operations becoming less feasible. Morbidity and mortality rates for surgery after induction therapy may be greater,^{30,56} and for an early-stage cancer, given the expected relatively good survival, the risks may well exceed any tangible benefit. Despite these concerns, several groups are pursuing rigorous induction strategies and demonstrating excellent safety profiles.^{57,58}

Induction Chemotherapy for Early-Stage Non-Small Cell Lung Cancer

Observations from other solid tumor treatment trials suggest that chemotherapy response rates improve as similar drug regimens are applied to earlier stages of disease.⁵⁹ The feasibility of induction chemotherapy for early-stage lung cancer was demonstrated in 2000 by the Bimodality Lung Oncology Team study.⁵⁰ This phase II trial examined the response, toxicity, resectability rate, surgical morbidity, and intermediate survival for patients treated preoperatively with carboplatin and paclitaxel. Two preoperative cycles were administered and three postoperative cycles planned for patients undergoing complete resections. After induction therapy, 56% of patients had a major objective response; 86% of patients underwent complete resection. An impressive percentage, 96%, of patients received the intended preoperative chemotherapy, and 46% received the planned postoperative courses. Treated patients appeared to have normal postoperative recoveries.

The results of a more recent randomized trial suggest a benefit of induction chemotherapy for stages I and II NSCLC.³⁰ The induction regimen consisted of two cycles of mitomycin, ifosfamide, and cisplatin. Two additional cycles were given postoperatively for responding patients. The patient population was heterogeneous, with some stage IIIA patients included in the study. Nonetheless, despite a slightly higher mortality rate for chemotherapy-treated patients, disease-free survival was longer than for untreated patients with stage I or II cancers. However, postoperative platinum-based chemotherapy in stage II and no adjuvant therapy for stage I remains the preferred approach.¹⁹

Induction Therapy for Stage IIIA/B Non-Small Cell Lung Cancer

In 1982, Pearson and colleagues reported on the dismal outcome of surgery alone for stage IIIA (N2 lymph node-positive) patients.⁶⁰ They noted a 9% 5-year survival rate

for gross mediastinal lymph node involvement and a 24% survival rate for patients with microscopically positive nodes. Even for occult, single-station N2 disease, the best reported survival rate is less than 30% after 5 years.⁶¹ Local recurrence seldom contributes to mortality, because most of these patients die of metastatic disease. Consequently, induction chemotherapy as the systemic component of multimodality treatment for patients with locally advanced NSCLC has been investigated.

By the mid-1990s, the recognized standard of care for resectable stage IIIA (N2-positive) NSCLC was changed by the near-simultaneous publication of two small randomized trials designed to study the efficacy of induction chemotherapy followed by resection. Until this time, most had considered combined definitive chemoradiotherapy as the standard of care. Collectively, these two reports represented data acquired from only 120 patients. Rosell and associates⁶² compared surgery alone with three cycles of induction chemotherapy (platinum based) followed by surgery. All patients in the study were scheduled to receive postoperative thoracic irradiation. A second, more chemotherapy-intensive trial consisted of three cycles of a cisplatin regimen given as induction with three additional cycles planned postoperatively for responding patients.⁶³ In this trial, radiotherapy was reserved for unresectable or incompletely resected patients. Entry into either trial required pathologic confirmation of mediastinal lymph node involvement (N2 disease) by mediastinoscopy, or T3 disease. Although neither study was without shortcomings, both trials were stopped early because interim analyses demonstrated a significant advantage favoring patients given induction chemotherapy. Mature, actual (not actuarial) survival updates have been published, with an average of 7 years of follow-up and these results appear to hold up.^{64,65}

In 2012, the results from the Chemotherapy for Early Stages Trial (CHEST) were reported.⁶⁶ This study sought to capitalize on the results from EORTC 08955 in which gemcitabine and cisplatin induction therapy had produced response rates of 70% and almost 19-month median survival.⁶⁷ CHEST was terminated early because of enrollment, but even with this limitation demonstrated an absolute difference at 3 years of 5.1% progression free survival and 7.8% overall survival benefits.⁶⁶ Taken together, these reports document a durable and statistically significant survival benefit of induction chemotherapy with surgery versus surgery alone, and they translate into a 20% better 5-year survival rate.

Induction Chemoradiotherapy

Radiotherapy in sequence after chemotherapy (with or without surgery) has long been used to consolidate the local component of therapy for stage III NSCLC.⁶⁸⁻⁷⁰ Concurrent chemoradiotherapy has several theoretical advantages over the sequential strategy. Contemporary drugs active in NSCLC (e.g., cisplatin, paclitaxel) are radiation sensitizers and allow a synergistic tumoricidal effect when given concurrently with ionizing radiation. Although combined therapy is clearly more toxic,⁷¹ several investigators have found the subsequent operative mortality and morbidity rates to be similar to those of

induction chemotherapy alone if appropriate perioperative safeguards and patient selection are optimized.^{56,72} A hypothetical advantage of concurrent chemoradiation induction therapy is reduction in tumor bulk, permitting unresectable lesions to be removed with negative margins, or the potential for lesser resections to be performed (lobectomy as opposed to pneumonectomy). Finally, delivery of ionizing radiation when tumor vascularity has not yet been disrupted by surgical dissection may enhance response.

Since 1990, the standard of care for patients with unresectable stage IIIA disease (bulky N2 involvement), and for most patients with stage IIIB NSCLC, has been concurrent chemoradiotherapy.⁷³ Based on encouraging observations with regard to clinical response rates but a disappointing rate of local failure, trials were devised to examine the addition of surgery to provide “more definitive” local control.⁷⁴ The Southwest Oncology Group (SWOG) organized the most widely reported, multi-institutional feasibility trial of this strategy, SWOG 8805. The treatment protocol consisted of two cycles of induction chemotherapy (cisplatin and etoposide) and 45 Gy of concurrent radiotherapy for patients with stage IIIA or IIIB NSCLC.⁷⁵ Of the 126 patients enrolled, 60% had stage IIIA and 40% had stage IIIB disease. Fifty-three percent of the stage IIIB patients had N3 lymph node involvement. A 6% operative mortality rate resulted, even though almost one third of the operations required pneumonectomy.⁷⁶ This compared favorably with contemporary surgical series without induction therapies,^{77,78} and it underscored the possibility of safely performing resection after combined neoadjuvant therapy.⁷⁵ This notion has since been reaffirmed by more recent studies.^{57,58}

Stage IIIB disease with N3 lymph node involvement is generally considered inoperable because of an inability to obtain a complete resection and a near-universal pattern of systemic failure after aggressive local therapy. Growing experience with surgery after induction chemoradiation has allowed certain centers to offer resection to selected stage IIIB patients. In SWOG 8805, patients with stage IIIA and IIIB disease had equivalent clinical and pathologic responses and similar survival rates.⁷⁵ These investigators and others⁷⁹⁻⁸² noted that only patients who had sterilization of their mediastinal disease after induction treatment benefited from treatment. For patients experiencing complete pathologic responses (i.e., no viable tumor found in the resected specimen), a 40% to 55% 5-year survival rate is expected.^{72,82} Because of this, more recent therapeutic regimens have attempted to improve the preoperative sterilization rate by increasing the dosage of radiation in the induction chemoradiation treatment to greater than 5900 cGy.^{57,58}

A single-institution experience using hyperfractionated radiotherapy with concurrent induction chemotherapy (cisplatin and paclitaxel) has identified an intermediate prognostic group.^{83,84} Patients with stage IIIA/B disease who were treated with this regimen were equally likely to benefit whether they had N2 or N3 disease before treatment (Figure 19-1). Patients downstaged from N3 to N2, or those IIIA patients with residual N2 disease at surgery, still had a median survival rate of 27 months and a 31% 5-year survival rate.⁷²

FIGURE 19-1 ■ Pre- (A) and post-induction (B) chemoradiotherapy chest computed tomographic images in a patient with stage IIIA non-small cell lung cancer (NSCLC). Note the reduction in size of the primary lesion and peritumoral ground-glass opacity after therapy.

A few recent randomized studies of induction chemotherapy and chemoradiotherapy for stage IIIA NSCLC question the usefulness of surgery as part of any treatment algorithm. In SWOG 8805, 21% of resected patients had a complete pathologic response with sterilization of primary lesion and regional lymph nodes (i.e., primary T0N0). An additional 37% of patients had only microscopic residual cancer.⁷⁵ Such observations led some investigators to speculate whether resection actually contributed to survival at all or merely provided prognostic information of response to therapy.

To address whether surgery benefits patients with stage III NSCLC, the National Cancer Institute sponsored a multi-institutional phase III trial (INT 0139), in which 429 patients received two cycles of cisplatin and etoposide with concurrent thoracic radiotherapy (45 Gy), followed by either resection or additional chemoradiation therapy. Resected patients were scheduled for two postoperative cycles of chemotherapy, whereas patients randomized to the no-surgery arm were to receive uninterrupted radiation up to 61 Gy with two additional cycles of chemotherapy. Although there were more early deaths in the surgical arm (14 versus 3), disease-free survival rates were superior when resection was a component of treatment (log-rank, $P = 0.02$). The 3-year survival rate in the operated group was 29% compared with only 19% in the chemoradiation-alone cohort.⁸⁵ The outcomes update, however, did not demonstrate a clear survival advantage for the whole group, although subgroup analysis showed a benefit favoring addition of surgery when the resection was lobectomy and not pneumonectomy.⁸⁵

Another randomized trial of induction chemotherapy followed by either resection or definitive radiotherapy demonstrated equivalence of the two treatment arms.⁸⁶ The 5-year overall survival rates were 15.7% and 14% for surgery and radiotherapy, respectively. The authors were left to conclude that, because of the lower

side-effect profile and lower treatment-related mortality, radiotherapy, and not surgical resection, should be considered the preferred locoregional treatment for these patients.

Current investigative efforts to enhance survival in patients with stage III disease are focused on novel induction chemotherapy drug combinations, different dosage schedules and intensities, altered radiation fractionation schemes, and the use of biological response modifiers targeting inflammation, angiogenesis, tissue invasion, cellular proliferation, apoptosis, and metastasis.⁸⁷⁻⁸⁹

Surgery remains central in the accurate staging of these patients and enhances survival for some patients with stage IIIA or IIIB NSCLC. Unfortunately, no patient or tumor characteristics can predict response to induction therapy. Moreover, clinical, noninvasive, and radiographic assessments of response have been disappointing.⁷⁰ Semiquantitative positron emission tomography (PET)^{90,91} and some minimally invasive techniques (e.g., endoscopic ultrasound-guided fine-needle aspiration,⁹² VATS,⁹³ repeat mediastinoscopy^{94,95}) may permit identification of patients most likely to benefit from resection after induction therapies. Nonresponders might be best served by alternative or experimental therapies.

For these reasons, the optimal treatment of patients with stage III NSCLC remains undefined. Although the role of surgery is unclear and the impact of improved post-induction staging unknown, it is clear that complete resection can provide improved long-term outcomes in appropriately selected patients.^{96,97}

Special Circumstance: Superior Sulcus Tumors

Patients with superior sulcus (Pancoast) tumors represent a unique group who serve as attractive candidates for induction protocols. The biological behavior of some of

these tumors seems to differ from that of other NSCLC in that extensive local disease can occur without the obligate systemic disease that accompanies other T3 tumors.⁹⁸ Nonetheless, presence of regional lymph node involvement remains a powerful negative predictor of survival after Pancoast tumor resection. In approximately one third of Pancoast tumor resections, complete resection is not obtained.⁹⁹ This is significant because an incomplete resection does not benefit the patient.⁹⁹⁻¹⁰²

Long-term survival after resection of a superior sulcus tumor was first observed only after the addition of adjuvant radiation therapy.¹⁰³ Subsequently, an induction radiation therapy strategy was developed that dramatically improved survival compared with historical controls.¹⁰⁴ Despite these advances, complete resection for node-negative T3 tumors was possible in less than two thirds of patients. Unlike standard stage II/III disease, locoregional disease was the most common form of recurrence.¹⁰⁵

The feasibility of induction chemoradiation therapy for patients with superior sulcus tumors was evaluated in a 2001 multi-institutional trial.¹⁰⁶ The study population included patients who had N2/N3 node-negative disease with T3 or T4 tumors and adequate cardiopulmonary fitness to tolerate resection. Patients were given two cycles of cisplatin and etoposide with concurrent radiation (45 Gy). The radiation field included the primary tumor and ipsilateral supraclavicular fossa, but it excluded the hilum or mediastinum. Surgery was performed 3 to 5 weeks after the end of the induction therapy. Two cycles of “boost” (adjuvant) chemotherapy were scheduled after recovery from surgery.

The induction therapy was completed as planned in 92% of patients. The related mortality rate was 3%. Of the enrolled patients, 75% underwent surgery. Of these, 92% underwent complete resection. The 2-year survival for completely resected patients was a surprising 70%. Updated mature results of this phase II trial demonstrated a 44% 5-year survival for the entire cohort

and a 12% local relapse rate versus 40% for historical controls.^{106,107}

RECOMMENDATIONS

The extent of NSCLC at initial diagnosis, as defined by American Joint Committee on Cancer staging,¹ is currently the only reliable predictor of survival. It is therefore essential to exhaust all reasonable efforts to obtain accurate staging information before consideration of adjuvant or induction therapies. Multimodality therapy should be used in a stage-dependent manner, guided and coordinated by a multidisciplinary team. This is summarized in Table 19-1.^{19,20}

Staging protocols must include a thorough search for distant metastatic disease and provide accurate information regarding locoregional lymph node involvement. We currently favor using PET as part of the metastatic survey and prefer mediastinoscopy for evaluation of mediastinal lymph nodes, although we recognize that endoscopic and endobronchial staging modalities are rapidly becoming an equivalent standard of care. Our institutional experience with PET to stage the mediastinum has not measured up to that reported elsewhere^{108,109} and has not replaced invasive mediastinal staging for this purpose in our practice.

There is little doubt that adjuvant chemotherapy has a role in the management of resected stage II/III NSCLC and is the standard of care at this time.^{19,20} Chemotherapy should revolve around a platinum-based regimen, and it is becoming increasingly apparent that patients benefit most when the intended dose of chemotherapy is delivered.

There is still active debate regarding the use of adjuvant chemotherapy for stage IB disease. Ongoing trials should help clarify this issue, although on the basis of current data, adjuvant chemotherapy for patients with stage I tumors should not be used.¹⁹

TABLE 19-1 Summary of Multimodality Guidelines

Stage	Surgery	Adjuvant Therapy	Radiation	Chemotherapy	Level of Evidence
I	Yes	No	No	No	1B—Surgical resection 1B—Against postoperative chemotherapy 1A—Against postoperative radiation therapy
II	Yes	Yes	No	Yes	1B—Surgical resection 1A—Postoperative chemotherapy 2A—Against postoperative radiation therapy
IIIA (N2-occult)	Yes	Yes	May be considered	Yes	1A—Adjuvant chemo 2C—Adjuvant radiation
(N2-discrete)	Yes	No	Yes (Definitive or induction recommended)	Yes	1A—Definite or induction followed by surgery 1C—Against primary resection followed by adjuvant therapy
IIIB (N2, N3)	No	No	Yes (Definitive concurrent)	Yes	1A—Definitive concurrent 1A—Against induction followed by surgery

Patients with stage IIIA/B NSCLC do poorly with surgery alone. After numerous studies and much debate, the optimal use of induction chemoradiation therapy remains largely unresolved. Although recent randomized trials do not favor the inclusion of surgery, complete resection can provide improved long-term outcomes in appropriately selected patients.^{96,97}

SUMMARY

INTRODUCTION AND HISTORY

Lung cancer continues to be the leading cause of cancer-related deaths in both men and women. Over 75% of non-small cell lung cancer (NSCLC) is advanced in stage at presentation, with extensive locoregional disease or distant metastasis. Most resectable lung cancers are confined to the pulmonary parenchyma, but 5% to 8% extend beyond the lungs and invade the pleura, soft tissues, or osseous structures of the chest wall.^{1,2} Chest wall invasion for surgical staging (T3) is defined as any tumor involvement into or beyond the parietal pleura. Pathologists can further describe these tumors by their depth of chest wall invasion, but this is infrequently reported in this subset of T3 patients.

Historically, chest wall invasion by a tumor of any histology was considered unresectable. Early surgical experience demonstrated that the surgical violation of the parietal pleura resulted in a sucking chest wound with immediate pulmonary collapse, often leading to the rapid demise of the patient. Dr. M. Michellau presented to the Institute of France in Paris in March of 1818 with a fungating mass protruding from his left chest wall. Dr. Richerand proposed a resection of the involved rib and pleura, an unprecedented operation at that time. On March 31, 1818, Dr. Richerand resected the left sixth and seventh ribs of Dr. Michellau with an unexpected occurrence of acute respiratory distress on entrance into the chest cavity. The patient was saved by covering the aperture with a linen cloth plastered with cerate. Despite a

rocky postoperative course, Dr. Michellau survived and returned home 27 days postoperatively. The pathology of the lesion is not known, but a primary rib malignancy is suspected.³

In the summer of 1883, a brilliant young surgeon, H. M. Block, in what was then called Danzig, East Prussia (now Gdansk, Poland), carried out the first planned pulmonary resection. Dr. Block had performed successful open chest surgery on experimental animals and was eager to apply his experience to humans.⁴ He chose a young female relative with a diagnosis of bilateral pulmonary tuberculosis and performed a thoracotomy to resect her diseased lung. Although the details of the operation are not known, we do know that the operation had a tragic end. A few days later, the short, brilliant career of Dr. Block ended with a self-inflicted gunshot wound to the head.⁵

Murphy⁶ described his experiments and clinical experiences with open pneumothorax during his address to the American Medical Association in 1898. Parham,⁷ in 1898, was the first in the United States to report resection of a bony chest wall tumor involving three ribs. A controlled pneumothorax with soft tissue coverage was created. This patient survived, although many others who followed did not.

The difficulties of operating with an opened pleural space in a spontaneously breathing patient were all too apparent to the surgeons of those times. Working without adequate control of the airway and ventilator support was difficult, and the patient quickly deteriorated once the

chest was open. Many ideas were investigated to overcome these deficiencies of the anesthetic techniques.

Major surgical and anesthesia advances were introduced in 1904 at the German Surgical Congress in Berlin. Two techniques, designed to surmount the open chest problem, were proposed. Ferdinand Sauerbruch,⁸ from the surgical clinic of von Mickylykz at the University of Breslau, introduced his method of *unterdruck* (low-pressure) ventilation. Lung expansion was maintained after thoracotomy by keeping an experimental animal's entire body inside a negative-pressure chamber (at -15 cm H_2O) while the head remained outside the chamber with the anesthesiologist. Brauer⁹ described the benefits of *uberdruck* (high-pressure) anesthesia, in which the lung was kept expanded by placing the patient's head in a glass positive-pressure chamber.

Surprisingly, the *unterdruck* method initially was the preferred technique. Sauerbruch and von Mickylykz built a negative-pressure operating room large enough to accommodate an entire surgical team, in which successful thoracic operations were carried out. These rooms continued to be built as late as 1918 in Munich by Sauerbruch, making this approach the favored method in Germany throughout the 1930s. Sauerbruch's ideas and methods so dominated his associates and contemporaries that little progress in other anesthetic techniques issued from Germany during this era.

Major progress, however, had already begun and would continue in France, England, and the United States during roughly the same period. The use of positive-pressure ventilation of the lungs was slowly being developed. Reliable delivery of positive pressure to the lungs was possible only by direct intubation of the trachea, and at that time, a tracheotomy was the only technique for tracheal intubation. Most surgeons were unwilling to perform a tracheotomy simply to deliver an anesthetic under positive pressure. The first systematic use of intubation through the mouth using bellows to inflate the lung was by the Frenchman DePaul, who intubated and resuscitated neonates in the mid-1800s. Other French surgeons, Tuffier, Quenu, and Doyen, and Milton in Egypt, also used positive pressure during thoracotomies in the last few years of the 19th century.

In the late 1800s, two physicians from New York, Joseph O'Dwyer and George Fell, described intubation techniques and positive-pressure ventilation. Dr. O'Dwyer developed a practical method of endotracheal intubation for the treatment of diphtheria, which was applied in thousands of cases and resulted in a gratifying decrease in the mortality rate of that dreaded disease.^{10,11} Dr. Fell also used a crude device to maintain ventilation in patients suffering from drug overdoses.¹² In New Orleans, Parham and Matas used the combined Fell-O'Dwyer apparatus in 1886 to administer positive-pressure surgical anesthesia.¹³

The use of positive-pressure ventilation identified the need for cuffed endotracheal tubes for the reliable delivery of anesthesia to the lungs. Eisenmenger first described a cuffed endotracheal tube in 1893. Placement of such tubes was facilitated by Kirstein,¹⁴ who introduced direct laryngoscopy in 1895 for safe, reliable placement of endotracheal tubes in the trachea. In 1907, Chevalier

Jackson improved the laryngoscope and produced the instrument that is still in use today and bears his name.¹⁵ A practical endotracheal tube design for general use was introduced by Guedel in 1928,¹⁶ and its use became widespread starting in the 1930s. In 1938, the first operative use of ventilators was made with the Freckner Spiropul-sator, developed in Sweden. In 1942, Griffith and Johnson, in Montreal, Canada, introduced curare to facilitate intraoperative controlled ventilation.¹⁷

With these international advances in intubation techniques and airway management, positive-pressure anesthesia slowly became a clinical reality during the last few years of the 19th century and the first few decades of the 20th century. As a direct result, surgeons were now willing to transgress the parietal pleura to address the complex pathologies of the thoracic cavity with increasing frequency. From 1904 to 1929, surgeons began to specialize and perform a series of pulmonary resections, and by 1929, thoracic surgery had become an established specialty. Most early lung resections and thoracoplasties were performed because of infections. Surgical morbidity and mortality rates were horrifying at first, and only the bravest patients and the most resilient surgeons chose to continue to work in the field. Sepsis was the predominant cause of death and was correlated mainly with an open pleural cavity.

In 1947, Coleman¹⁸ reported long-term survival after en bloc excision of the chest wall with pulmonary resection. Concurrently, significant strides in chest wall reconstructive techniques were occurring through the use of fascia lata grafts, autogenous rib grafts, large cutaneous flaps, and latissimus dorsi muscle flaps, as described by Campbell in 1950¹⁹ and Grillo et al in 1966.²⁰ Over the past 40 years, we have witnessed further refinements in surgical procedures, the use of prophylactic antibiotics, improved anesthesia delivery and monitoring, and the implementation and use of critical care units for postoperative ventilation. Today these advances permit the safe and effective resection of locally advanced lung cancer with extensive chest wall involvement on a routine basis.

Pancoast tumors comprise a distinct surgical entity and are discussed separately.

DEMOGRAPHICS AND SYMPTOMS

Patients with lung cancer are usually 50 to 70 years old; lung cancer is rarely seen in patients younger than 30 years, although with the ongoing epidemic of children and young teenage smokers, advanced lung cancer can be seen even in these younger age groups (Fig. 20-1). Lung cancer with chest wall invasion most typically presents in patients in their seventh decade, with a median age of 64 to 66 years (range, 38-93 years).²¹⁻²³ Overall, lung cancer incidence and mortality continue to be disproportionately higher in men than in women, although the gap is narrowing. Lung cancer with chest wall invasion has an overwhelming predominance in men; women represent only 10% to 30% of patients in several recent studies.^{2,21-23} Current or previous smoking history is elicited in approximately two thirds of patients, with an average 50-pack-year history per patient.^{2,21}

FIGURE 20-1 ■ **A**, A 25-year-old woman presents to our institution with a nonhealing thoracotomy incision with a draining wound after an attempted decortication for what was initially felt to be a postpneumonic empyema. **B**, A CT scan demonstrates a large right lower lobe adenocarcinoma of the lung with direct invasion of the chest wall as the cause of the nonhealing wound.

The lung parenchyma has no sensory nerve fibers, which accounts for the often late clinical presentation of most bronchogenic tumors. Most patients have presenting symptoms related to compression, invasion, or obstruction of the lung parenchyma or airways, or invasion of the chest wall or mediastinal structures. Metastasis to distant organs, including neurologic symptoms and bone pain, unfortunately are common.

Patients whose lung cancer has invaded the chest wall have similar presenting symptoms, including chest pain (40%-60%), cough (14%), recurrent lower respiratory tract infection (10%-25%), weight loss (10%-18%), hemoptysis (12%), and dyspnea (11%). As many as 25% of patients can be asymptomatic (Table 20-1).^{2,21,22}

TABLE 20-1 Presenting Symptoms in Lung Cancers with Chest Wall Invasion

Presenting Symptom	Percentage
Chest wall pain	40%-60%
Recurrent lower respiratory tract infection	10%-25%
Weight loss	10%-18%
Hemoptysis	12%
Dyspnea	11%
Cough	11%
Asymptomatic	25%

The right lung has a slight predominance in location of lung cancers, both in general and for those with chest wall invasion.² Okada and colleagues described a marked predilection for the upper lobes in his series of lung cancers that invade the chest wall, although not all series confirm this finding.²³ Lung cancers in general have a slight predilection for upper lobes rather than lower lobes, which theoretically may be related to the relative increase in ventilation (and associated carcinogens) to the upper portions of the lungs.

Squamous cell carcinoma is the classic smoking-related tumor, and for many years it was the most common histology. In recent years, however, adenocarcinoma has overtaken squamous cell carcinoma as the most common lung cancer worldwide. Several series of patients with lung cancer that invades the chest wall have demonstrated that the histologic diagnosis of squamous cell carcinoma remains the most common, followed closely by adenocarcinoma; large cell carcinoma and adenosquamous carcinoma comprise fewer of these tumors.^{2,22-24} Average tumor diameter in these patients, by computed tomography (CT) measurements, was 6.5 cm; tumors ranged from 2 to 18 cm in maximum diameter.²

DIAGNOSIS

Chest roentgenography is useful for the identification of parenchymal lesions, although it has poor specificity and sensitivity for detecting chest wall involvement. Rib destruction is a reliable indicator of chest wall invasion, although it is identified on routine chest x-rays in only a fraction of cases. Tissue diagnosis of malignancy in these T3 lesions usually is obtained by transthoracic needle aspiration by our interventional radiologists.

Peripheral lung lesions with the suggestion of chest wall involvement may require additional radiographic testing to confirm invasion. These radiographic techniques include CT scans, nuclear medicine (scintigraphic) bone scans, magnetic resonance imaging (MRI), and positron emission tomography (PET) scans. Although gross tumor involvement of the chest wall is easily diagnosed with these radiographic modalities, confirmation of isolated parietal or mediastinal pleural invasion is more difficult and often unreliable.²⁵⁻²⁸

The use of CT scans has greatly increased the precision of tumor localization, allowed accurate evaluation of contiguous organ involvement, improved assessment of lymph nodes, and improved the identification

of pulmonary metastasis. A CT scan is excellent for assessing rib destruction and intercostal muscle tumor extension but is relatively inaccurate for invasion limited to the parietal or mediastinal pleura.^{25,26,28} Shirakawa and associates²⁹ identified patients who had parietal pleural invasion by using inspiratory/expiratory CT scans. They demonstrated that a respiratory phase shift of greater than half of a vertebral body height in middle and lower lobe tumors reliably predicted the absence of parietal pleural invasion. The accuracy and negative predictive value were 90% and 86%, respectively, in tumors located in the lower and middle lobes. For upper lobe tumors, however, the respiratory phase shift did not correlate with operative findings regardless of whether invasion was present. This discrepancy is a result of the minimal normal respiratory phase shift of these lung fields when the patients were studied in the supine position.

MRI has the advantages of multiplanar imaging and high differential signal intensity, which are invaluable for determining vascular invasion and spinal involvement. Conventional MRI, unfortunately, is just as limited as CT scans for evaluation of parietal and mediastinal pleural invasion. Kodalli and associates²⁷ used breath-hold inspiration and expiration MRI to assess parietal pleural invasion. Pleural invasion was excluded when tumor displacement exceeded 5 mm in reference to chest wall structures or relevant mediastinal structures (e.g., the aortic arch).

This study identified 100% sensitivity and specificity for pleural invasion for tumors located in the middle lobe and basilar segments of the lower lobes. Studies of upper lobe tumors and those located in the apical segments of the lower lobes demonstrated a positive predictive value of only 40% but a negative predictive value of 100%. The superiority of MRI to CT scans lies in its ability to assess lung and diaphragm movement in a coronal plane. Insufficient respiratory motion is evident by less than 1-cm movement of the diaphragm on coronal images, and necessary scans could be repeated by asking the patient to take a deeper breath. Although more recent reports have also commented on high sensitivity, specificity, and accuracy of respiratory dynamic cine MRI in evaluating lesions that do not have clearly demonstrated invasion on standard CT or MRI, this modality is not widely available outside of specialized centers.³⁰

Ultrasonography (US) has been compared with CT for detection of chest wall involvement. In a series from 2008, 90 patients with suspicion for chest wall involvement were evaluated preoperatively with CT and US. Their ultrasound criteria for determining chest wall invasion were any two of the following: (1) tumor ingrowth seen into the chest wall, (2) interruption of the pleural reflection, (3) invasion of the ribs, (4) impairment of movement with respiration. Based on these criteria, US was deemed more sensitive than CT (89% vs. 42%) with similar specificity (95% vs. 100%).³¹ Perhaps the real-time imaging of ultrasound during respiration leads to more accurate imaging data.

More invasive methods have been used for detection of parietal pleural invasion, including use of expiratory dynamic CT scans after the introduction of a diagnostic pneumothorax.^{32,33} Lack of invasion was diagnosed on the

basis of appearance of an air space between the mass and adjacent structures. Sensitivity was 100% in both studies for chest wall invasion, although sensitivity dropped to 76% in cases of mediastinal invasion.

Specificity for tumor involvement was 80% in a study by Watanabe and coworkers.³² Benign pleural adhesions caused false-positive results. Complications were reported as mild and included chest pain, shortness of breath, and subcutaneous emphysema. Despite these results from a variety of imaging techniques, we do not feel that these tests are warranted because they potentially subject high-risk patients to a pneumothorax and ultimately are unlikely to alter the planned operative procedure. In some cases, review of the CT images obtained during transthoracic needle biopsy can reveal minimal pneumothoraces incidentally obtained as a result of biopsy. Often, these images will show clear separation from the chest wall (Fig. 20-2).

For most patients, preoperative assessment of chest wall involvement is not critical, because it does not often alter resectability or treatment strategy. However, for the marginal patient, who may be borderline for toleration of lung resection, identifying chest wall invasion, and thus the necessity for combined pulmonary and chest wall resection, may lead the clinician to pursue definitive non-operative treatment with chemoradiotherapy.

STAGING

Accurate staging of NSCLC is critical for effective clinical management. Standard staging includes a complete history and physical examination, laboratory tests (including calcium, alkaline phosphatase, and liver function tests), chest x-ray, CT scan of the chest and upper abdomen to include the adrenal glands, and full body PET scan. In addition, brain MRI is obtained when a patient has neurologic symptoms or when the lesion is locally advanced or nodal disease is suspected.

Surgical-pathologic staging is performed according to the International Staging System for Lung Cancer, using information about the primary tumor (T), nodal status (N), and distant metastasis (M) (Table 20-2).³⁴ “T” status denotes characteristics of the primary tumor, including size and local aggressiveness. Chest wall invasion denotes at least T3 status (for a full description of TNM staging, refer to the most current AJCC Lung Cancer Staging guidelines). “Chest wall involvement,” however, includes a wide pathologic spectrum, from invasion of the parietal pleura only to full-thickness chest wall replacement by tumor.

Nodal status (N) comprises the second feature of the staging system. Clinical evidence of ipsilateral hilar node involvement is classified as N1, which is not considered a contraindication for surgical resection. Ipsilateral adenopathy of the mediastinum increases the nodal status to N2. The most effective treatment modality for these patients is controversial and is discussed later. Spread of tumor to the contralateral mediastinal, contralateral hilar, or any scalene or supraclavicular nodal basins denotes an N3 status; patients with N3 disease generally are not considered surgical candidates.

FIGURE 20-2 ■ A CT of the chest reveals a lung mass abutting the posterior rib (arrow in left image). A review of the images obtained during transthoracic needle biopsy showed the mass moving away from the chest wall with a minimal focal area of pneumothorax (arrow in right image). Other images revealed complete separation from the chest wall. Note: The patient is prone in these scans for obtaining the biopsy.

TABLE 20-2 Brief Description of the TNM Stage Groups for Lung Cancer						
Stage 0	Carcinoma in situ					
Stage IA	T1a,b	N0	M0			
Stage IB	T2a	N0	M0			
Stage IIA	T1a,b, T2a	N1	M0	T2b N0 M0		
Stage IIB	T2b	N1	M0	T3	N0 M0	
Stage IIIA	T3	N1	M0	T1-3	N2 M0	T4 N0-1 M0
Stage IIIB	T4	N2	M0	Any T N3 M0		
Stage IV	Any T	Any N	M1a,b			

Patients without evidence of distant metastatic disease are considered to have M0 disease, and they may be candidates for surgical resection. However, in patients with distant metastatic disease (M1), systemic treatment in the form of chemotherapy is currently the treatment of choice, often in combination with radiation therapy for local control.

In 1997 an important change was made to the TNM staging system regarding tumors with chest wall involvement. Before 1997 a NSCLC that was defined as T3 N0 M0 was classified as stage IIIA. Survival data of patients with these tumors revealed that their clinical course with surgery alone was more favorable than the clinical course of other patients with stage IIIA disease (i.e., those with hilar or mediastinal lymph node involvement; T3N1, T3N2, T1N2, or T2N2). Subsequently, T3 N0 M0 tumors had been downstaged to stage IIB with this revision.

Because the survival rate of lung cancer patients with chest wall involvement and nodal disease is significantly worse than that of patients with chest involvement alone, the clinical challenge for surgeons is to identify nodal involvement by noninvasive imaging or minimally invasive biopsy techniques before subjecting patients to extensive chest wall resections.

The importance of correct pretreatment staging cannot be overemphasized. Hilar and mediastinal lymph nodes can be assessed before surgery by using CT scans, MRI, and PET scans. Integrated CT-PET scans measure metabolic activity of tissues and can detect disease in

otherwise normal size-appearing nodal tissue; however, the accuracy for subcentimeter nodules is reduced.

Despite advances in nuclear imaging techniques, mediastinoscopy remains the most sensitive and specific test for evaluating the mediastinal nodes and should be considered before undertaking any major chest wall resection. Another option available for staging the mediastinum is endobronchial ultrasound (EBUS)-guided fine-needle aspiration. EBUS involves the use of a specially designed bronchoscope with an ultrasound transducer at the tip that allows real-time image guided biopsy of nodes adjacent to the airway and can access some nodes at levels 10, 11, and 12.^{35,36} Sensitivity and specificity of EBUS have been reported to be higher than those of CT or PET and comparable to those of mediastinoscopy; in addition, it is less invasive.³⁷ Because of the anatomic location, the preoperative assessment of N1 disease is more problematic via mediastinoscopy. Patients with T3N1 disease still should be considered for en bloc resections, and these patients have a better survival rate than those with N2 disease.

Flexible bronchoscopy is performed for transbronchial biopsies, brushings, and washings. Although it is unlikely that peripheral lung tumors involving the chest wall extend into the airway, it is the authors' practice to perform bronchoscopy immediately before resection to identify any unsuspected endobronchial disease and to assess the airway anatomy.

Bone scintigraphy scans can be used to detect occult bony metastases and confirm bony lesions in symptomatic

patients. The vertebral column is the most commonly affected region for bone metastases. MRI is accepted as the most accurate imaging modality in detecting bone metastases within the vertebral column, and focal imaging can be guided by bone scan abnormalities or symptoms.³⁸⁻⁴⁰ Suspicious uptake in bones other than the vertebral column also requires further investigation, although MRI scans become less useful. False positives are seen in the bony thorax when a history of rib fractures or trauma is noted. False negatives can be appreciated when bone scans are correlated with PET scans. Positive lesions on PET scans, which are not seen on bone scans, may represent soft tissue metastasis.⁴¹ Durski and associates⁴¹ recommend that all patients be staged with a PET scan, and bone scans should be performed only if symptomatically indicated when PET scans are negative. In their series, the use of bone scans in addition to PET scans did not change the clinical stage of any of their patients, although it allowed more precise localization of skeletal abnormalities.

PET scans using ¹⁸F-fluorodeoxyglucose (FDG) are routinely used in addition to CT scans for both initial diagnosis and staging of NSCLC. One study suggests that obtaining both a PET and a CT scan is more cost-effective than performing a CT scan alone for staging.⁴² The reported sensitivity and specificity of PET for thoracic lymph node involvement are 70% to 100% and 81% to 100%, respectively. CT has sensitivity and specificity of 25% to 81% and 56% to 94%, respectively.⁴³⁻⁴⁷ The ACOSOG trial Z0050 evaluated the usefulness of PET for staging NSCLC. Their results support staging NSCLC patients with PET to reduce the rate of non-therapeutic thoracotomy but recommend confirming PET-positive mediastinal nodes with mediastinoscopy. In addition, their recommendations include using PET to guide tissue biopsy in the cases of suspected single-site distant metastases.⁴⁸ Integrated PET-CT was compared with PET alone in a prospective blinded trial in which the same radiologist read an integrated scan and, at a later date, was asked to read the PET images only. Integrated PET-CT was shown to be more accurate at predicting T and N status of patients and was better at determining stage I and stage II disease.⁴⁹ Integrated scans have become standard for preoperative evaluation of all our NSCLC patients.

TREATMENT

Patients with confirmed N2 disease who are devoid of distant metastatic disease are offered treatment on protocol with neoadjuvant chemotherapy. Surgery is offered to those patients whose tumors show an objective response to chemotherapy and whose disease can be completely resected.²² Progression of disease while on chemotherapy is generally regarded as a contraindication to surgery, as is evidence of N3 disease. Preoperative radiation therapy has not been shown to increase survival in several studies but has demonstrated an increased operative mortality.^{1,22,50} Preoperative radiation therapy therefore is not widely used and is not recommended at our institution.

Patients with evidence of metastatic spread should not be considered surgical candidates except in extraordinary circumstances. These circumstances may include isolated brain metastases that can be resected before lung resection.

PREOPERATIVE ASSESSMENT

The most important risk factors for perioperative complications for patients who are undergoing resection of lung tumors are cardiovascular and pulmonary disease, metabolic disorders (e.g., diabetes), and malnutrition. A complete preoperative assessment therefore includes physiologic testing for cardiac and pulmonary reserve, optimal management of diabetes, and nutritional support when needed. Spirometry, arterial blood gases, alveolo-capillary diffusion (D_{LCO}), and xenon ventilation scans determine pulmonary reserve and predict postoperative function. Cardiac evaluation—including electrocardiography (ECG), echocardiography, stress testing, and even cardiac catheterization—may be required to identify correctable disease in high-risk patients. Nutritional assessment includes aggressive diabetic control, optimization of protein stores, and possible enteral or parenteral feeds for severely malnourished patients. Serial measurements of prealbumin levels may be used as a guide to nutritional improvement.

The overall effect on chest wall mechanics and respiratory physiology must be taken into account when evaluating the medical condition of the patient and the extent of pulmonary resection. Most surgeons try to leave a patient with at least 33% of predicted forced expiratory volume in one second (FEV_1) postoperatively. Spirometry, xenon scanning, and exercise oxygen testing are helpful in identifying patients who are truly medically inoperable based on these pulmonary function criteria. No tests, however, can accurately predict the postoperative pulmonary compromise of patients who require chest wall resections. It is often difficult to predict the extent of required rib resections and the requirement for chest wall stabilization and reconstruction. Phrenic nerve or diaphragmatic involvement may lead to further impaired respiratory physiology. Occasionally, in patients with marginal lung function, a nonanatomic or subsegmental resection of the lung may be required if the chest wall component of the operation is extensive.

OPERATIVE TECHNIQUES

Good communication and cooperation with our anesthesia and pain management colleagues is crucial to the success of these operations. Several pain management and anesthetic techniques have dramatically improved the intraoperative and postoperative course for our patients. A plan for adequate pain control, either with epidural catheters or long-acting local anesthetics with non-narcotic and narcotic analgesics, is of vital importance to prevent postoperative morbidity. In addition, a double-lumen endotracheal tube is useful for these cases and greatly facilitates visualization during the surgery.

In most patients, the tumor can be approached via a posterolateral thoracotomy. In tumors that involve the chest wall and the apex of the chest (either superior sulcus tumors proper or large upper lobe tumors with chest wall and neck extensions), an initial anterior neck approach to dissect the subclavian vessels and the brachial plexus may be beneficial before addressing the posterior chest wall component (Fig. 20-3). Depending on the tumor location, the incision may be tailored more posteriorly and extended superiorly between the scapula and spinous processes. Review of the radiographic studies and palpation of the interspaces should identify an intercostal space

at least one rib space below the inferior margin of the tumor for entry into the chest cavity. On entry into the hemithorax, digital examination of the lung and chest wall is performed to determine tumor attachment and assess chest wall fixation. The chest cavity is examined for pleural dissemination or metastatic deposits at other sites. Great care should be taken to prevent disruption of thin adhesions of the tumor to the parietal pleura that may be involved with tumor.

When tumor invasion into the chest wall is radiographically evident before surgery, an en bloc chest wall resection should be carried out with at least one

FIGURE 20-3 ■ **A**, Chest radiograph demonstrating a large right upper lobe apical tumor, which was diagnosed a sarcomatoid carcinoma based on transthoracic needle biopsy. **B**, A CT scan demonstrates the full-thickness chest wall involvement with tumor extension into the posterior chest wall musculature. **C**, A mediastinoscopy is performed routinely to rule out N2 or N3 nodal involvement before proceeding with the extensive lung and chest wall resection. **D**, An initial supraclavicular neck dissection is performed to dissect the subclavian vessels and brachial plexus. This is the initial hockey-stick skin incision along the anterior border of the sternocleidomastoid muscle and along the clavicle. **E**, A close-up of the resection of the first and second ribs from the anterior approach with resection of the subclavian vein and preservation of the subclavian artery and brachial plexus as shown.

FIGURE 20-3, cont'd ■ **F**, The patient is repositioned. The initial dissection is through a posterolateral thoracotomy with elevation of the scapula after division of the latissimus dorsi muscle and reflection of the serratus anterior muscle. The tumor bulge into the interspaces of the chest wall can be appreciated. There is no gross tumor involvement of the external surface of the chest wall, however. **G**, An interspace is entered caudal to the inferior extent of the tumor involvement. **H**, The posterior elevation of the paraspinous muscles and disarticulation of the posterior ribs from the transverse processes and vertebral bodies. **I**, Complete en bloc removal of the chest wall (ribs one to five) and the right upper lobe.

uninvolved rib and intercostal muscle above and below the mass.⁵¹ An en bloc resection is defined as removal of lung parenchyma in continuity with a portion of the adjacent parietal pleura and chest wall soft tissues. The overlying integument generally is left intact, although complete extension of tumors through the skin can be seen (Fig. 20-4).

On rare occasions when the tumor is large, its bulk can impede the exposure of the hilar structures. In this situation, several firings of a stapler through normal, uninvolved pulmonary parenchyma can permit the initial removal of the tumor and chest wall, with safer dissection of the delicate hilar vessels without the risk of torsion and traction created by the weight of the tumor and attached chest wall. An en bloc resection is preferred whenever it is feasible.

It is more difficult to determine the extent of malignant pleural involvement when the adhesions are thin and filmy between the tumor and the chest wall. The tumor may be somewhat mobile on palpation. A surgeon must resist the temptation to simply lyse these adhesions. An extrapleural dissection must be initiated away from the site of attachment. If the plane is not easily identified at any time during the extrapleural dissection, then the extrapleural dissection must be immediately halted and a full-thickness chest wall resection performed. If the extrapleural dissection appears to proceed easily, frozen section analysis of the parietal pleura is recommended.² If the tumor transgresses the parietal pleura on frozen section, then an additional resection of the chest wall is required. When performing an extrapleural dissection, marking the extent of the extrapleural dissection with

metal clips on the chest wall leaves a permanent radiographic landmark to guide adjuvant radiotherapy if required.

Circumferential margins of 2 cm generally are regarded as adequate, although some surgeons advocate

FIGURE 20-4 ■ A 75-year-old man with a fungating tumor in the left anterior chest wall originating from a bronchogenic carcinoma of the lingula with transmural invasion of the chest wall and skin.

a larger margin of 4 cm on the rib resection.^{21,52} In these studies the mean number of ribs resected was three, with a range of one to five.^{2,21} The oncologic resection should never be compromised by less than a complete resection.

Several circumstances deserve additional mention. Special attention needs to be paid to tumors extending into the intervertebral foramen without intraspinal extension. Disarticulation of the ribs is performed through the costotransverse joints with ligation of the nerve roots as they exit the spinal column.⁵³ Tumors that extend into the vertebral column may require a laminectomy to expose the epidural tumor and involved nerve root. The tumor is dissected free from the dura, and the nerve roots are identified and transected. In cases where the tumor invades the vertebral bodies themselves, a partial resection of the vertebral body may be performed without the need for instrumentation. Resection should be carried out to grossly uninvolved bone and can include complete vertebrectomy with spinal reconstruction (Fig. 20-5). Further discussion regarding vertebral resection and reconstruction is beyond the scope of this chapter.

Anterior tumors that invade into the sternum are resected en bloc with the involved portion of the sternum and attached ribs. A complete resection is mandatory and

FIGURE 20-5 ■ **A**, A lateral chest radiograph demonstrating a large right upper lobe lung cancer with involvement of the chest wall and T1 through T3 vertebral bodies. **B**, Operative positioning of the patient with the head in cervical tongs to immobilize it and to maintain the alignment of the cervical and thoracic spines. The patient is additionally secured on a beanbag and taped with the appropriate padding of the anterior superior iliac spine. **C**, Intraoperative photograph showing the resected chest wall, right upper lobe, and multilevel vertebral body resection with reconstruction with posterior rods and anterior stabilization. **D**, Chest radiograph posteroanterior demonstrating postoperative instrumentation.

may necessitate a complete sternectomy. Reconstruction with a rigid prosthesis to prevent flail usually is required after a complete sternectomy. If the resection is limited to either the manubrium or less than one third of the sternum, reconstruction is often unnecessary.⁵⁴

The resected portion of the chest wall remains attached to the lung and is allowed to drop into the hemithorax, where pulmonary resection is then carried out in the usual manner. The extent of pulmonary resection is determined by the amount of parenchymal involvement, as well as the pulmonary reserve of the patient. A crucial determinant for long-term survival is the ability to achieve a complete (R0) resection.¹ The survival rate of patients who undergo incomplete resection (R1) is comparable to that of patients who have not had a resection at all.¹ Most frequently, lobectomy is sufficient to achieve an R0 resection.

Burkhardt and associates,²¹ in 95 operations for bronchogenic carcinoma with chest wall involvement, performed a lobectomy in 80% of patients in their series, pneumonectomy in 13%, bilobectomy in 4%, and sublobar resection in 3%. Okada,²³ in his series of 132 patients, favored a more lung-preserving approach, with 49% undergoing lobectomy, 15% segmentectomy, 13% sleeve lobectomy, 10% pneumonectomy, 8% lobectomy with partial resection, and 5% sleeve bilobectomy or sleeve pneumonectomy. In both series a complete mediastinal and hilar lymph node dissection was performed in each patient. In all cases the operating surgeon confirmed the clinical impression of an R0 resection. In our practice we would agree with the general recommendation to perform a complete mediastinal and hilar nodal dissection in these patients.

Recent reports have described en bloc chest wall resections and anatomic pulmonary resections using completely minimally invasive thoracoscopic techniques, or thoroscopes as an adjunct to assist in the resection.⁵⁵⁻⁵⁷ The basic principles of oncologic resection should remain the same as with more traditional techniques.

RECONSTRUCTION

Reconstruction of the chest wall defect is controversial. Some surgeons do not routinely reconstruct chest wall defects in any patients, and they report minimal morbidity. Facciolo and associates² performed 104 thoracotomies with full-thickness chest wall resection without prosthetic reconstruction of the costal elements in any patient. Chest wall defects were closed with scapula repositioning or chest wall muscle transfers. Exact details regarding location and complexity of the defects were not described, although the results were excellent.

In general, all full-thickness skeletal defects that have the potential for paradox should be considered for reconstruction. Both the size and location of the chest wall resection should guide the decision for reconstruction. When the defect is small, approximately 5 cm or less, the skeletal component can be ignored and the defect closed with overlying soft tissues only. Posterior defects up to 10 cm in diameter may not require reconstruction because the overlying scapula provides support.

Exceptions include midthoracic posterior defects that allow the scapular tip to become entrapped in the bony thorax during full range of motion of the ipsilateral arm. In these cases either the chest wall can be reconstructed or the scapular tip can be amputated.

Many complex chest wall defects require not only skeletal stabilization but also skin and soft tissue coverage to protect the reconstruction. Indications for reconstruction include the need for structural stability, cosmesis for anterior and lateral chest wall defects, obliteration of dead space, and recruitment of healthy soft tissue from nonanatomic areas to restore the chest wall integrity.

Reconstruction can be performed using autogenous tissues, such as fascia lata grafts or muscle transpositions, or various prosthetic materials, including mesh, metals, or soft tissue patches. The use of autogenous tissue is favored when the wound to be closed is contaminated. Grossly contaminated wounds may need to remain open for a period of time for aggressive local wound care before attempted closure, sometimes at the expense of prolonged mechanical ventilation.

The most commonly used autogenous grafts are locally advanced muscle flaps. Although transposition of the latissimus dorsi muscle for chest wall coverage was described in 1896 by Tansini, it was Brown and associates who reintroduced the musculocutaneous concept in 1977 and created a surge of interest in muscle and musculocutaneous flap reconstruction of the thoracic cavity.⁵⁸ The use of muscle flaps should be anticipated before surgery, and the operation should be conducted to protect the muscle of choice and its vascular pedicle at all times (Fig. 20-6).

The most widely used local muscle flaps are the latissimus dorsi, pectoralis major, rectus abdominis, serratus anterior, trapezius, and deltoid muscles. The latissimus dorsi muscle has excellent versatility because of its large size and wide arc of motion, allowing it to reach both the anterior and posterior thorax. The pectoralis major muscle also displays great versatility, with significant limitations seen only when posterior thoracic coverage is needed. In those cases it can be used as a free flap. Less frequently, the transverse rectus abdominis musculocutaneous (TRAM) flap is used. It is used almost exclusively for anterior defects and is rotated about its vascular pedicle.

When muscle flaps are not available or cannot be used, prosthetic materials are used. Because of the availability and easy handling of synthetic materials, many surgeons prefer to use synthetic grafts for reconstruction even if muscle flaps are available. The choice of prosthetic material can vary, but the type of material used often depends on the surgeon's preference. LeRoux and Shama have set forth the ideal characteristics of a prosthetic material: rigidity to abolish paradoxical chest motion, inertness to permit ingrowth of fibrous tissues and decrease the likelihood of infection, malleability so that it can be fashioned to the appropriate shape at the time of the operation, and radiolucency to allow for follow-up of the underlying problem.⁵⁹

Additional desirable features include hypoallergenicity, lack of proven carcinogenicity, the ability to withstand sterilization, the ability to not be modified by bodily

FIGURE 20-6 ■ **A**, Chest radiograph posteroanterior demonstrating a large squamous cell carcinoma of the left upper lobe involving ribs one through seven. Mediastinoscopy was negative. **B**, Lateral operative positioning with the entail skin incision raised for muscle flaps. **C**, Operative photo demonstrating extensive chest wall resection of seven ribs with en bloc left upper lobe attached. **D**, Resulting surgical chest wall defect with previously mobilized muscle flaps (latissimus, serratus, and pectoralis) that are used to cover the prosthetic chest wall reconstruction.

fluids, and adequate strength. Although no substance to date perfectly fulfills all of these criteria, various synthetic and alloplastic materials can be used with satisfactory results.

Polypropylene mesh (PM) (Marlex, Cranston, RI) with or without methylmethacrylate sandwich, polytetrafluoroethylene (PTFE) mesh, and Vicryl mesh are

examples of materials that have been used in different situations. PTFE is made in a variety of thickness sizes; 2-mm thickness is required for chest wall reconstruction to tolerate the tension generated during closure. Some surgeons consider PTFE to be easier to handle than PM because it lends itself to a slight stretch, can be sutured with fewer wrinkles and surface irregularities, and may

create a watertight seal of the pleural space.⁵⁴ However, Deschamps and associates⁶⁰ compared PM to PTFE and observed no significant differences in outcomes or complications.

Polypropylene mesh with methylmethacrylate (PPMM) sandwich provides the most rigidity and perhaps the best cosmetic result, at the price of greater difficulty of implantation. In cases where the chest wall resection is extensive and the possibility of paradoxical movement of the reconstruction is suspected, this level of rigidity is desired. A few key points need to be kept in mind when working with this unyielding material. After the specimen is removed, the patient is returned to a neutral position by unflexing the operating table if initially flexed on positioning. An imprint of the defect is made to determine the size of the reconstruction, and the mesh is tailored to leave approximately 2 to 3 cm of extra material circumferentially with which to secure the patch to the remaining chest wall. A thin layer of methylmethacrylate is applied directly to the mesh, leaving 2 to 3 cm of mesh circumferentially overlapping the chest wall and free of cement. The layer of cement should not extend completely to the edges of the ribs, but leave at least one centimeter gap. If the cement is allowed to extend to the rib edges, respiratory motion and movement of the torso can lead to undesirable and often painful "clicking" of the movement of the unyielding solid prosthesis against bony elements of the chest wall. A second layer of mesh, of identical size, is quickly applied to the cement, thereby creating the "sandwich." The cement generates a significant amount of heat as it hardens, so care must be taken to avoid contact with unprotected tissue. When the reconstruction is of the lateral chest wall, it is important to re-create the curvature of the thorax. This may be accomplished by allowing the sandwich to harden on a malleable retractor that has been shaped appropriately or by allowing the sandwich to harden on the patient's (protected) iliac crest.

Regardless of the material used, the patch is secured taut with heavy interrupted nonabsorbable sutures either through or around the remaining ribs. If the spine constitutes the posterior border of the defect, the sutures may be placed through drill holes in the transverse processes. The patch is then covered with adequate healthy soft tissue. Intrathoracic chest tubes are tunneled a distance from the reconstruction and positioned to avoid direct contact with the synthetic material. Subcutaneous closed suction drains should be used when extensive flaps have been raised and a large potential dead space has been created.

The simplest and most practical method of coverage is local tissue advancement. This is particularly important in patients who have received high doses of radiation; the local tissues may have impaired healing potential, and in many cases rotation of a pedicled muscle flap from a nonradiated area may be advantageous. There are occasional cases in which the local muscle flaps may be unavailable because the muscles have been extirpated or the vascular pedicle has been destroyed by surgical ablation or irradiation. In those cases free tissue transfer of flaps using microvascular reconstruction can be used with excellent results.⁶¹ Often these complex cases require the

close interaction of the thoracic surgical team with our plastic surgeon colleagues. Available grafts can include contralateral latissimus dorsi and serratus anterior muscles, as well as both ipsilateral and contralateral TRAM flaps.⁶¹ The omentum is an excellent salvage flap that can be used in cases where the pedicled muscle flap fails. Suction drains frequently are used to eliminate dead space or are used in cases of large raw surfaces over the prosthetic reconstruction. Drains usually are removed when the daily output is less than 25 mL/day from each drain.

Titanium plating systems are also available for reconstructing chest wall defects, either alone or in conjunction with soft tissue or synthetic materials. The multiple titanium plates can be used to span a defect to provide skeletal stability and prevent paradoxical chest wall movement. These are secured to healthy bone with drill and screw systems, prior to coverage with soft tissue. The same precautions against infection must be used as with implantation of any synthetic material, but results from initial reports for reconstruction of sternal and chest wall resections appear to be satisfactory in short follow-up.^{62,63}

Lung tumors that involve the chest wall are exceedingly rare in children, but children present a unique challenge to the thoracic surgeon when reconstruction is necessary. Depending on the age of the child, growth of the chest wall continues, thereby limiting the ability to use prosthetic materials for reconstruction. As the child outgrows the reconstruction, the mesh may cut through its anchors and re-create the defect. If a more solid reconstruction is used, permanent mesh can act as a tether, eventually leading to contracture and deformity. Tuggle and colleagues have reported successful chest wall reconstruction using bioabsorbable copolymer plates in four children. This material has been used for cranial and facial reconstruction in the pediatric population. They cite benefits that include excellent tensile strength, moldability, and resorbability, which would leave residual firm fibrous tissue but theoretically not limit growth. Their report in this limited series indicates follow-up to only 2 years without instability or growth limitation at that point.⁶⁴ Ideally reconstruction should be performed with rotational muscle flaps whose nerve supplies are carefully preserved, to allow for growth and a dynamic contribution to chest wall development.⁶⁵

POSTOPERATIVE CARE

Postoperative care should be tailored to each individual patient. A patient with good preoperative pulmonary function who had a limited resection and reconstruction should be extubated in the operating room at the conclusion of the case and convalesced on a telemetry ward. A frailer patient with an extensive resection and reconstruction may require intubation for 24 to 48 hours in the intensive care unit, with meticulous respiratory hygiene. For all patients the authors prefer to continue epidural analgesia either until the chest tubes are removed or up to 7 days after surgery, whichever comes first. Aggressive pulmonary hygiene, including early ambulation, incentive spirometry, and bronchodilators, is essential and is

attended by a full-time respiratory therapy staff on the wards. All patients remain on telemetry monitors throughout their hospital stay. The use of antibiotics postoperatively usually is limited to 24 hours of a broad-spectrum cephalosporin. Chest tubes are removed when air leaks have been sealed and when drainage is less than 100 mL per 8-hour shift. Additional postoperative care is similar to that of other thoracotomy patients.

COMPLICATIONS

Complications specific to chest wall resection and reconstruction include wound seroma formation, wound infection involving the prosthesis, and respiratory mechanical changes subsequent to prosthetic placement.^{60,66} Small seromas are best managed with observation because most resolve with time. Large or symptomatic seromas can be repeatedly aspirated under strict sterile conditions with little risk of contamination. Surgical obliteration is infrequently necessary and is reserved for recalcitrant seromas.⁶⁰

Wound infections that occur with synthetic grafts usually require removal of the prosthesis and replacement with either autogenous reconstruction or open wound care with delayed closure. Prolonged air leaks from violated visceral pleural surfaces or fissures can allow respiratory bacteria to infect the overlying prosthesis. Every attempt must be made to seal or oversee any raw lung surfaces and decrease the remaining free space within the hemithorax before placement of the prosthetic material. In all pulmonary resections, including the upper lobes, the inferior pulmonary ligament should be divided to permit sufficient mobility of the remaining lung in the hemithorax. Chest tubes should be placed in the hemithorax, minimizing their direct contact with the mesh. PM is preferable to PTFE when significant air leaks are present. The smooth surface of PTFE often makes it more difficult for a lung prosthesis apposition to occur and can result in a localized bronchopleural fistula that declares itself months later. PM permits more vigorous adhesions, leading to rapid ingrowth of the lung, and is better suited for a “contaminated” environment of an air leak.

The development of a bronchopleural fistula after pneumonectomy is an extremely morbid complication to treat, and in cases with chest wall resection and synthetic reconstruction, the treatment options are limited and complex. Most cases require removal of the prosthesis and prolonged open wound care. Patients who survive the initial sepsis and demonstrate signs of wound healing may be considered for complex reconstructions, which may include muscle flaps, omental flaps, and even thoracoplasty. Frequently these complicated cases are best handled using a multispecialty approach, with the aid of talented plastic surgeons familiar in reconstructive techniques.

Delayed wound infections can occur as a result of seroma aspiration or hematogenous seeding from distant infection. In these cases careful inspection of the prosthesis in the operating room is required. Most early prosthesis infections require removal of the prosthesis,

followed by local wound care. In infections that present months after the primary surgery, removal of the prosthesis without replacement is often well tolerated without pulmonary compromise. After several months, sufficient fibrous tissue has developed to support the chest wall mechanics. Delayed wound infections may have had adequate time for incorporation of the prosthesis by granulation tissue, especially polypropylene, making prosthesis removal difficult and even unnecessary. Deschamps and associates⁶⁰ allowed those prostheses that were well incorporated by granulation tissue to remain in situ, using aggressive wound débridement and frequent dressing changes. They were able to salvage approximately one half of these infected reconstructions without removal of their prosthesis and without development of delayed wound infections or draining sinus tracts.

In rare cases, complications may occur related to mechanical failure of the prosthesis, with patch dehiscence resulting in lung herniation, or flail physiology. We had encountered one case in which a particularly active young patient fell and fractured his PPMM prosthesis, resulting in uncomfortable clicking and instability. This necessitated replacement (Fig. 20-7).

Postoperative respiratory mechanical changes often are difficult to measure, and they vary based on the type of prosthesis used. The loss of viscoelasticity and inhomogeneity is a result of the replacement of a dynamic chest wall with a rigid structure that prevents chest wall mobility. Animal studies suggest that PTFE is favorable to PPMM because it allows the chest wall to remain dynamic during the respiratory cycle.⁶⁶ Human studies are limited but demonstrate good pulmonary function 6 months postoperatively. Lardinois and associates⁶⁷ studied patients preoperatively and 6 months postoperatively and found no significant deterioration of FEV₁, and they noted concordant chest wall to prosthesis movements in most patients.

Cerebrospinal fluid (CSF) leaks can occur when the dura is violated during dissection within the intervertebral foramina or during partial or complete

FIGURE 20-7 ■ An active young patient cracked his polypropylene-methylmethacrylate chest prosthesis. The instability and the uncomfortable clicking necessitated replacement.

vertebrectomies. The nerve roots should be ligated distal to the emergence of the external sheath covering the cord. Potential spinal fluid leaks should be carefully evaluated during the initial operation. If a small dural tear has occurred during the resection, it needs to be repaired with fine monofilament sutures and covered with an autogenous tissue transfer using intercostal muscle, diaphragm, or pleura. Negative intrathoracic pressure coupled with positive pressure created in the CSF can lead to a chronic CSF leak. Initial treatment includes a lumbar drain and patient immobility in a supine position to minimize the CSF pressure. Supine bed rest of a post-thoracotomy patient can be associated with significant pulmonary complications.

Caution with hemostasis around the vertebral foramina is of paramount importance. Excessive use of monopolar electrocautery in this region could lead to transmitted cautery current with nerve or even spinal injury; judicious use of bipolar cautery is warranted. Aggressive packing of oxycellulose to control hemorrhage at an intervertebral foramen has led to a report of paraplegia caused by swelling of the oxycellulose. Fortunately this was reversible with immediate reoperation, removal of the oxycellulose and coverage with fibrin glue, and a pericardial fat pad.⁶⁸

Patients who have required extensive combined lung and chest wall resections that extend to the vertebral bodies and dural sac can have fascinating delayed complications. For example, a patient in whom a small dural rent was identified and repaired during the resection of a tumor involving the vertebrae required a chest tube for 10 days for a prolonged air leak that occurred during the dissection of the interlobar fissure. The patient had no problems after the removal of the chest tubes and discharge from the hospital. Several months later, he had mental status changes and a seizure that was believed, on clinical grounds, to likely represent metastatic disease to the brain. A CT scan was done and demonstrated a significant amount of air within the brain (Fig. 20-8), which originated from a small bronchopleural subarachnoid fistula. This required an additional thoracotomy with interposition of a pedicled omental flap between the lung and the dural sac to close the small communication. Within 48 hours, the patient's neurologic status normalized.

PATHOLOGY

A complete resection (R0) is defined as pathologic evidence of disease-free (negative) tissue margins on final pathology and an assessment by the surgeon that all grossly detectable disease, including nodal disease, has been removed. Patients who had complete gross resection at thoracotomy but were found to have positive margins on final microscopic pathologic review are classified as having undergone an incomplete (R1) resection. Gross residual disease after an attempted resection is classified as an R2 resection, including residual nodal disease that could not be removed.

Depth of chest wall invasion can be grouped into three levels on the basis of the final pathologic examination:

FIGURE 20-8 ■ A CT scan of the brain demonstrating the pathognomonic finding of air within the ventricular system of the brain (arrows) secondary to a bronchopleural-subarachnoid fistula from a combined chest wall, lung, and vertebral body resection.

parietal pleura only; parietal pleura and soft tissues; and parietal pleura, soft tissues, and bone. Complete pathologic stage (TNM) is based on microscopic examination of the primary mass, all surrounding margins, and nodes.

The evaluation of the world literature pertaining to chest wall resections in patients with lung cancer often is complicated, based on varied surgical practices. Some surgeons proceed directly to en bloc full-thickness chest wall resections rather than attempting to strip the parietal pleura by extrapleural maneuvers. In Facciolo and associates' series of 104 patients who underwent full-thickness, en bloc resections of lung with attached chest wall, the pathologic depth of invasion was limited to parietal pleura only (in 27% of patients), parietal pleura and soft tissues (35%), and parietal pleura, soft tissue, and bone (38%).² All margins were microscopically negative on final pathologic review. All lymph nodes were negative in 80% (N0), 5% had positive hilar or lobar nodes (N1), and 15% had positive mediastinal (N2) nodes.

Chapelier and associates⁶⁹ also exclusively performed full-thickness resection of any tumors found by the naked eye to be invading at least the parietal pleura. A total of 100 patients were treated by this method. Pathologic evaluation revealed parietal pleural invasion in 29% of cases, parietal pleura and intercostal muscle invasion in 47% of cases, and osseous invasion in 24% of cases. Microscopically negative margins were attained in all but one patient. Nodal status was 65% N0, 28% N1, and 7% N2.

Burkhart and associates²¹ reviewed their experience with 95 resections with bronchogenic carcinoma with invasion of the chest wall, all treated with full-thickness chest wall resection. Depth of invasion extended into the

parietal pleura only in 31% of patients, into the parietal pleura and soft tissues in 45% of patients, and into the osseous structures in 24% of patients. Seventeen percent of patients had pathologically involved N1 nodes, and 15% had pathologically involved N2 nodes. A presumed R0 resection was obtained in all cases.

Downey and associates¹ reported on 334 patients who underwent thoracic exploration for T3 tumors involving the chest wall at Memorial Sloan Kettering Hospital. Intraoperative results included 175 patients who achieved an R0 resection, 94 who achieved an R1 or R2 resection, and 65 who underwent exploration only. Of the 175 patients who attained an R0 resection, 80 (46%) underwent an extrapleural resection based on intraoperative surgeon judgment of the level of invasion. All 80 had evidence of parietal invasion only. The remaining 95 patients underwent full-thickness chest wall resection, of which 19% had parietal pleural invasion, 25% had parietal pleural and soft tissue invasion, and 56% had invasion involving the osseous structures.

Magdeleinat and associates²² attempted an extrapleural resection in all patients whose parietal pleura could be easily removed. Intraoperative frozen sections were obtained when any doubt existed about negative margins. Tumors fixed to the deeper structures were removed with the associated full-thickness chest wall. A total of 201 patients were studied, of which 89 (44%) had tumor invasion limited to the parietal pleura. Ten of these patients underwent a full-thickness chest wall resection because the surgeon suspected deeper invasion intraoperatively. Only one patient who underwent an extrapleural resection had an underestimation of invasion, with microscopic residual identified at final pathology. Thirty-four patients (17%) did not achieve an R0 resection, most often because of residual tumor at the lateral edges of the resection. Nodal disease was absent in 58% (N0), lobar or hilar nodal disease was seen in 26% (N1), and mediastinal nodal disease was seen in 13% (N2). Three percent of patients had T4 disease.

Pathologic staging with standard histopathologic evaluation has been augmented with the use of immunohistochemical (IHC) stains to detect micrometastatic disease in lymph nodes and at resection margins. Mineo and colleagues analyzed nodes and margins of their en bloc lung and chest wall resections ($N = 47$) with IHC stains and found over 10% of patients had only margins positive on IHC, which strongly correlated with local failure, and 12% had only nodal micrometastases seen on IHC staining, which correlated with distant relapse.⁷⁰ None of their patients who were IHC positive in the lymph nodes or margins lived to the 4-year follow-up, whereas those who were node negative and margin negative by IHC had a 73% 5-year survival. This appears to be a strong prognostic factor, but whether IHC detection of disease can lead to improved delivery of adjuvant therapy and subsequent survival advantage remains to be seen.

RESULTS

Operative mortality is defined as mortality within 30 days of surgery or within the same hospitalization. Improve-

ments in preoperative screening, anesthetic techniques, and postoperative care have decreased the incidence of postoperative mortality in many studies. Long-term results are affected most importantly by complete resection to microscopically negative margins and by absence of N2 nodal involvement.⁷¹ The extent (number of ribs) of chest wall resection is not a determinant for 5-year survival as long as an R0 resection is accomplished. These results are validated by several studies.

Overall complications and mortality in patients with combined pulmonary and chest wall resections are greater than of pulmonary resection alone. This is not only because of the added potential complications unique to chest wall resection but also because of the increased surgical insult and physiologic impairment from chest wall resection. A review by Martin-Ucar and colleagues from Leicester of their experience with lung and chest wall resection in 41 patients indicated increased 60-day mortality in those with any of the following: significant weight loss ($BMI < 18.5$), advanced age (>75 years old) and decreased preoperative FEV_1 ($<70\%$ predicted) with a 47% 60-day mortality for patients with one or more of the aforementioned risks, and 0% mortality for patients who did not have any of the three factors.⁷²

Weyant and colleagues reported on 262 chest wall reconstructions (141 were pulmonary resections with chest wall resection). In their series the greatest predictor of postoperative respiratory complications was the size of the chest wall resection, and they advocated rigid repair with PPM sandwich for physiologic stability of the chest wall. Although some groups have reported reasonable outcomes for patients undergoing pneumonectomy with chest wall resection,⁷³ they caution against it; in a series, four of nine patients who underwent pneumonectomy with chest wall resection died postoperatively.⁷⁴

Facciolo and associates² reported no operative mortality and a major complication rate of 20%, which included atrial fibrillation, bleeding, prolonged air leak, and empyema. Forty percent of patients received postoperative radiation therapy, and all patients with N2 disease received postoperative chemotherapy. The overall 5-year survival rate was 61%, with a median survival period of 74 months. Statistically worse 5-year survival rates were noted in patients with N2 disease when compared with patients with N0 disease (18% vs. 67%). Depth of invasion also affected survival rates, with a 79% survival rate at 5 years for pleural involvement only compared with a 56% survival rate for pleural, soft tissue, and bone involvement. An impressive 90% 5-year survival rate was noted in the subset of patients with N0 disease whose tumors were limited to the parietal pleural invasion only. The addition of postoperative radiation therapy dramatically increased 5-year estimated survival rates from 47% to 74%, although the criteria for administering postoperative radiation are not clearly defined.

Chapelier and associates⁶⁹ had different results. The operative mortality rate was 4%, and postoperative complications were noted in 16% of patients. The median survival period was 18 months, the 2-year survival rate was 41%, and the 5-year survival rate was 18%. Significantly worse 5-year survival rates were noted with N2

disease when compared with N0 or N1 disease (0% vs. 22% vs. 9%, respectively). Patients with more than two ribs resected had better survival rates when compared with patients with fewer than two ribs resected ($P=0.03$). Invasion limited to the pleura only was an independent factor favoring long-term survival when compared with deeper invasion ($P=0.02$). The long-term survival rate for patients with well-differentiated tumors was significantly better than that for patients with poorly differentiated or undifferentiated tumors ($P=0.005$). Postoperative radiation therapy or adjuvant chemotherapy did not improve survival in this study.

Burkhardt and associates²¹ summarized the Mayo Clinic experience, with somewhat higher mortality and morbidity rates. The operative mortality rate was 6.3%, and the complication rate was 45%. The overall 5-year actuarial survival rate was 39%, with best survival rates noted in stage IIB (T3 N0 M0) patients (44%), and worse rates for stage IIIA patients (26%). Interestingly, women in their study had a significantly improved 5-year survival rate compared with men (53% vs. 39%, respectively), and women without evidence of nodal disease had the best survival rate (61% 5-year survival). Survival rates in all groups were affected by depth of invasion; tumors that invaded the parietal pleura only resulted in a 5-year survival rate of 50%, compared with 35% in patients with tumor invasion into the soft tissues and 31% in patients with osseous involvement. Although these results did not reach statistical significance, the trend is suggestive of results seen at other institutions. Of their patients, 10% received neoadjuvant chemotherapy and/or radiation therapy, with a disappointing increase in operative mortality rates noted in those patients who had received radiation. No improvement in survival rates was seen in pretreated patients.

Voltolini and colleagues⁷⁵ retrospectively analyzed outcomes of their lung resections with chest wall involvement in 68 patients. A multivariate analysis revealed that survival was impacted by nodal status, complete resection, and depth of chest wall invasion. Their node-negative patients had a 42% 5-year survival, but those who were node positive (N1 or N2) had 17% survival at 5 years. Those with tumors involving the parietal pleura had significantly better 5-year survival than those with deeper invasion (43% vs. 9%). They had three patients with positive margins; none lived to the 1-year follow-up.

Matsuoka and colleagues⁷⁶ reported similar conclusions with their experience of lung resections involving the chest wall. They also found poorer 5-year survival for N2-positive patients compared with node-negative patients (6.2% vs. 44%) and poorer survival for those with incomplete resections (14% compared to 34% for complete resections). They did not, however, find depth of chest wall invasion to correlate with outcome.

Doddoli and colleagues⁷⁷ in France reported their series of 309 patients from three institutions. In their experience lung resections involving the chest wall were associated with an 8% operative mortality rate and a 33% complication rate. They reported a 5-year survival rate for stage IIB (T3N0) patients of 40% but only 12% for stage IIIA (T3N1 or T3N2). In their population of stage IIB (T3N0) patients, en bloc resection afforded a better

5-year survival (60%) rate than did extrapleural resection (39%). The impact of R1 or R2 resection could not be determined because their series included only those with R0 resection. The Memorial Sloan Kettering Hospital experience, as summarized by Downey and associates,¹ is comparable with other reports. The operative mortality rate, including all patients who underwent surgery, was 3%. Patients who left the operating room with either R1 or R2 disease had a dismal 5-year survival rate of 4%, which was comparable to the survival rate of those patients who underwent exploration without resection (0%). Patients who received R0 resection had a 6% postoperative mortality rate and an overall 5-year survival rate of 32%. Further analysis in the R0 group demonstrated survival advantage in node-free patients; 5-year survival rate in T3 N0 M0 = 49%, T3 N1 M0 = 27%, and T3 N2 M0 = 15% ($P<0.0003$). After either complete extrapleural or en bloc resection, there was no significant difference in survival rates between histologic groups, nor was there any difference in survival rates by univariate analysis of pathologic demonstration of depth of tumor invasion in the chest wall. Overall there was no observed significant difference in survival rates after a complete extrapleural resection compared with after a complete en bloc resection. However, further subgroup analysis demonstrated that patients with N0 disease had a prolonged survival period when receiving an extrapleural resection versus an en bloc resection (65 months vs. 21 months, respectively, $P<0.01$). This conflicts with the aforementioned series by Doddoli where stage IIB patients had better survival with en bloc resection.⁷⁷ They also noted no survival advantage to radiation therapy given preoperatively, intraoperatively, or postoperatively.

Magdeleinat and associates²² documented a 7% operative mortality rate and a 36% complication rate. Predictably, perioperative complications were more frequent in older patients and in patients with limited pulmonary reserve. Actuarial 5-year and 10-year survival rates for the entire population were 21% and 13%, respectively. After complete and incomplete resection, 5-year survival rates were 24% and 13%, respectively. The highest survival rate was noted again in the subgroup of patients without nodal involvement. The authors noted an increased 5-year survival rate in patients whose tumor did not extend beyond the parietal pleura (37%) as compared with those whose tumor extended past the parietal pleura into the chest wall proper (15%). Of note, in patients with disease limited to the pleura, the type of resection (extrapleural or chest wall) did not affect survival rates (37% and 31%, respectively).

Elia and colleagues⁷⁸ from Italy reported similar outcomes in their 110 patients. They reported a 0% mortality rate and 28% complication rate. Again, nodal status was strongly correlated with 5-year survival (47% for N0 vs. 0% for N1 or N2) (Table 20-3). They also analyzed survival of their N0 patients by type of resection and found no difference in survival rate for extrapleural versus en bloc resection. The survival rate of patients who had R1 resections was not reported, and breakdown of survival by depth of chest wall involvement was not analyzed.

Lee and colleagues²⁴ recently reported the outcomes of 107 patients undergoing chest wall resection for NSCLC. Pneumonectomy was performed in 42% of these patients with a 5% operative mortality rate and a 21% complication rate. The 1-year mortality rate for survivors was 59%. Multivariate analysis found five main factors that were prognostic for survival: depth of invasion, tumor size, node status (N0 and N1 vs. N2), complete resection, and completion of adjuvant therapy. Comparison of outcomes between the various studies can be seen in Table 20-3.

SUMMARY

In summary, bronchogenic lung cancer with invasion into the chest wall is seen in less than 10% of patients with resectable disease. Extensive preoperative staging is required because metastatic disease is a contraindication for surgical treatment. Patients with N2 disease should not be considered candidates for primary surgical treatment. These patients should be considered for protocol treatments, when available, that may include neoadjuvant chemotherapy and/or radiation therapy followed by surgery if an appropriate response is seen.

The operative approach may include an extrapleural resection only when tumor invasion is limited to the parietal pleura, or it may include a more extensive en bloc resection when deeper soft tissue and bony chest wall invasion is demonstrated. The most important predictors of long-term patient survival are (1) the achievement of an R0 resection and (2) nodal status. Reconstruction generally is required for anterior and lateral defects when a flail segment is created and for large posterior defects that may cause a trapped scapula. Reconstruction options are numerous, including autogenous tissue flaps, rotational muscle flaps, and a variety of prosthetic materials. The choice of reconstruction is based on each patient and his or her clinical situation, surgeon preference, and the availability of specialized plastic surgical assistance.

Long-term results are encouraging in those patients who, after final pathologic review, are found to have N0 disease (stage IIB). The role of postoperative adjuvant

treatment in patients with incidental N1 or N2 (IIIA) disease is not defined.

RESULTS AND PROGNOSIS

HISTORICAL NOTE

Henry K. Pancoast, a radiologist at the University of Pennsylvania, described a patient afflicted with a carcinoma of uncertain histologic origin occupying the extreme apex of the chest, associated with shoulder and arm pain, atrophy of the hand muscles, and Horner syndrome.¹ This clinical entity has become known as Pancoast syndrome. Unknown to Pancoast, Tobias had already characterized the anatomic and clinical aspects of this lesion, correctly recognizing that the tumor was a peripheral lung cancer. Anatomically, the pulmonary sulcus refers to the costovertebral gutter extending from the first rib to the diaphragm. The superior pulmonary sulcus lies at the uppermost extent of this recess, as reviewed by Teixeira.² Generally, it is understood that non-small cell lung carcinomas of this region are termed Pancoast tumors, and we refer to this association throughout the chapter. However, the term *superior sulcus lesion* encompasses other, more diverse causes, both benign and malignant. Furthermore, this definition has been expanded to include patients who do not have evidence of brachial plexus or stellate ganglion involvement. Chest wall involvement in this region might be restricted to involvement of the parietal pleura or could extend deeper to the upper ribs, vertebral bodies, or subclavian vessels, according to Detterbeck.³ Invasion of the chest wall at or lower than the level of the second rib, or of the visceral pleura only, does not meet the criteria for a superior sulcus lesion. Additionally, Macchiarini and colleagues⁴ reported that a wide variety of superior sulcus lesions can result in Pancoast syndrome (Box 21-1); thus, a histologic diagnosis is mandatory when the syndrome is encountered.

PRESENTATION

Superior sulcus lesions of non-small cell histology account for less than 5% of all bronchial carcinomas, as reported by Ginsberg and associates.⁵ These tumors may arise from either upper lobe and tend to invade parietal pleura, endothoracic fascia, subclavian vessels, brachial plexus, vertebral bodies, or the first rib. However, their clinical features are influenced by their location.

Tumors located anterior to the anterior scalene muscle may invade the platysma and sternocleidomastoid muscles; the external and anterior jugular veins; the inferior belly of the omohyoid muscle; the subclavian and internal jugular veins, including major branches; and the scalene fat pad (Fig. 21-1). They invade the first intercostal nerve and the first rib more frequently than the phrenic nerve or superior vena cava. Patients usually complain of pain distributed to the upper anterior chest wall.

Tumors located between the anterior and middle scalene muscles may invade the anterior scalene muscle (phrenic nerve lying on its anterior aspect); the subclavian artery, including primary branches, except the posterior scapular artery; and the trunks of the brachial plexus and middle scalene muscle (Fig. 21-2). These tumors manifest with signs and symptoms related to the compression or infiltration of the middle and lower trunks of the brachial plexus (e.g., pain and paresthesia radiating to the shoulder and upper limb).

Tumors lying posterior to the middle scalene muscles are usually located in the costovertebral groove and invade the nerve roots of T1, the posterior aspect of the subclavian and vertebral arteries, the paravertebral sympathetic chain, the inferior cervical (stellate) ganglion,

BOX 21-1 Causes of Pancoast Syndrome**NEOPLASMS**

- Primary bronchogenic carcinomas
- Other primary thoracic neoplasms: adenoid cystic carcinomas
- Hemangiopericytoma
- Mesothelioma
- Metastatic neoplasms: carcinoma of the larynx, cervix, urinary bladder, and thyroid gland
- Hematologic neoplasms: plasmacytoma, lymphoid granulomatosis, lymphoma

INFECTIOUS PROCESSES

- Bacterial: staphylococcal and pseudomonal pneumonia, thoracic actinomycosis
- Fungal: aspergillosis,allescheriasis, cryptococcosis
- Tuberculosis
- Parasitic: echinococcosis (hydatid cyst)

FIGURE 21-1 ■ Computed tomographic scan showing a right superior sulcus bronchial carcinoma invading the anterior thoracic inlet, including the subclavian vein.

FIGURE 21-2 ■ Magnetic resonance image showing a left superior sulcus bronchial carcinoma invading the middle thoracic inlet, including the subclavian artery.

and the prevertebral muscles. Some of these posterior tumors can invade transverse processes (Fig. 21-3) or extend to the vertebral bodies (only those without intraspinal extension may be resected).

Because of the peripheral location of these lesions, pulmonary symptoms, such as cough, hemoptysis, and

FIGURE 21-3 ■ Computed tomographic scan showing a right superior sulcus bronchial carcinoma invading the posterior arch and the transverse process of the first rib and abutting the costovertebral angle.

dyspnea, are uncommon in the initial stages of the disease. Abnormal sensation and pain in the axilla and medial aspect of the upper arm in the distribution of the intercostobrachial (T2) nerve are more frequently observed in the early stage of the disease process. With further tumor growth, patients can develop overt Pancoast syndrome.

PREOPERATIVE STUDIES

Any patient with signs and symptoms that suggest the involvement of the thoracic inlet should undergo a detailed preoperative evaluation to establish the diagnosis of bronchial carcinoma and to assess for operability. These patients usually have small apical tumors that are hidden behind the clavicle and the first rib on routine chest radiographs. The diagnosis is established by history and physical examination, biochemical profile, chest radiographs, bronchoscopy with sputum cytology, fine-needle transthoracic or transcutaneous biopsy, and computed tomography of the chest. A tissue diagnosis via video-assisted thoracoscopy is rarely indicated when other investigations are negative; thus it eliminates the possibility of pleural metastatic disease. If there is evidence of mediastinal adenopathy on computed tomographic scanning and/or on positron emission tomography, mediastinoscopy is mandatory because patients with histologically proven N2 disease are not operative candidates most of the time.

Neurologic examination, magnetic resonance imaging (MRI), or electromyography may delineate the tumor's extension to the brachial plexus, phrenic nerve, or epidural space. Vascular invasion is evaluated by venous angiography, subclavian arteriography, Doppler ultrasonography (cerebrovascular disorders may contraindicate resection of the vertebral artery), or MRI (Fig. 21-4). If the workup suggests tumor encroachment into the intervertebral foramina, additional MRI is mandatory to rule out invasion of the extradural space (Fig. 21-5).

The initial evaluation also includes routine cardiopulmonary function tests and investigative procedures; positron emission tomography has become mandatory to

FIGURE 21-4 ■ Angiogram illustrating a massive tumoral invasion of the intrascapular left subclavian artery.

FIGURE 21-5 ■ Magnetic resonance image that rules out invasion of the intervertebral foramina by the tumor.

identify the presence of any metastatic disease that precludes surgical treatment.

TREATMENT

Tumors of the superior sulcus are deemed universally and rapidly fatal lesions. For many years, it was believed that these tumors were not amenable to surgery, until Chardack and MacCallum⁶ successfully performed a lobectomy and chest wall excision followed by radiation therapy. Eight years later, Shaw and colleagues⁷ approached superior sulcus tumors with preoperative radiation therapy (30 to 45 Gy in 4 weeks, including the primary tumor, mediastinum, and supraclavicular region) followed by surgical resection. This radiosurgical approach shortly became the standard treatment, yielding

better disease control and survival compared with other treatments. More recently, Ginsberg and colleagues⁵ provided evidence that en bloc resection of the tumor combined with external radiation (preoperative, postoperative, or both) must be considered the standard therapeutic approach for superior sulcus tumors. The goal of resection is the complete removal of the upper lobe in continuity with the invaded ribs, transverse processes, subclavian vessels, T1 nerve root, upper dorsal sympathetic chain, and prevertebral muscles.

In 1999, we reviewed various surgical approaches for treating superior sulcus lesions.⁸ In general, superior sulcus lesions not invading the thoracic inlet are completely resectable through the classic posterior approach of Shaw and colleagues.⁷ However, the posterior approach does not allow direct, safe visualization, manipulation, or complete oncologic clearance of all anatomic structures of the thoracic inlet. Superior sulcus lesions extending to the thoracic inlet should be resected by an anterior transcervical approach according to our previous description.⁹

This operation has been increasingly accepted as a standard approach for all benign and malignant lesions of the thoracic inlet. Additionally, this approach facilitates exposure of the anterolateral aspects of the upper thoracic vertebrae. Contraindications to this approach include extrathoracic metastasis, invasion of the brachial plexus above the T1 nerve root, invasion of the vertebral canal or sheath of the medulla, massive invasion of the scalene muscles or extrathoracic muscles, mediastinal lymph node involvement (multiple N2 disease), and advanced cardiopulmonary disease.

ANTERIOR TRANSCERVICAL TECHNIQUE

One-lung anesthesia with measurements of urine output and body temperature is necessary. An arterial line opposite to the primary lesion and at least two venous lines for volume expansion should be used. The patient is supine with the neck hyperextended and the head turned away from the involved side. A bolster behind the shoulder elevates the operative field. The skin preparation extends from the mastoid downward to the xiphoid process and from the midaxillary line laterally to the contralateral midclavicular line medially. An L-shaped cervicotomy incision is made, including a vertical pre-sternocleidomastoid incision carried horizontally below the clavicle up to the deltopectoral groove (Fig. 21-6). To increase the exposure, the interception between the vertical and horizontal branches of the L-shaped incision is lowered to the level of the second or third intercostal space, depending on tumor extent. The incision is then deepened with cautery. The sternal attachment of the sternocleidomastoid muscle is divided. The cleidomastoid muscle, along with the upper digitations of the ipsilateral pectoralis major muscle, is scraped from the clavicle. A myocutaneous flap is then folded back, providing full exposure of the neck and cervicothoracic junction.

Once the inferior belly of the omohyoid muscle is divided, the scalene fat pad is dissected and sent for

FIGURE 21-6 ■ Anterior transcervical approach. (As described in Darteville PG, Chapelier AR, Macchiarini P, et al: Anterior transcervical-thoracic approach for radical resection of lung tumors invading the thoracic inlet. *J Thorac Cardiovasc Surg* 105:1025, 1993.)

pathologic examination to exclude scalene lymph node metastasis. Inspection of the ipsilateral superior mediastinum after division of the sternothyroid and sternohyoid muscles is made by the surgeon's finger along the tracheoesophageal groove. Next, tumor extension to the thoracic inlet is carefully assessed. We recommend resection of the medial half of the clavicle only if the tumor is deemed resectable. The jugular veins are dissected first, so that branches to the subclavian vein can eventually be divided. On the left side, ligation of the thoracic duct is usually required. Division of the distal part of the external and anterior jugular veins facilitates visualization of the venous confluence at the origin of the innominate vein. The internal jugular vein may be ligated to increase exposure of the subclavian vein (Fig. 21-7) but can be conserved most of the time. If the subclavian vein is involved, it can be easily resected after proximal and distal control has been achieved. Direct extension of the tumor to the innominate vein does not preclude resection. Next, the anterior scalene muscle is divided with cautery either at its insertion on the scalene tubercle of the first rib or in a tumor-free margin (Fig. 21-8). If the tumor has invaded the upper part of this muscle, it needs to be divided at its insertions on the anterior tubercles of the transverse processes of C3 to C6. Before dealing with the anterior scalene muscle, the status of the phrenic nerve is carefully assessed because its unnecessary division has a deleterious influence on postoperative respiratory function. It should be preserved whenever possible.

The subclavian artery is dissected (Fig. 21-9). To improve mobilization, branches are divided. The verte-

FIGURE 21-7 ■ Illustration of the resected scalene fat pad and the internal half of the clavicle after division of the sternal head of the sternocleidomastoid and the inferior belly of the omohyoid muscles. The exposure, dissection, and division of the external and internal jugular vein greatly facilitates the exposure of the subclavian vein and permits assessment of tumor resectability. (Adapted from Darteville PG, Chapelier AR, Macchiarini P, et al: Anterior transcervical-thoracic approach for radical resection of lung tumors invading the thoracic inlet. *J Thorac Cardiovasc Surg* 105:1025, 1993.)

bral artery is resected only if invaded and if no significant extracranial occlusive disease was detected on preoperative Doppler ultrasound. If the tumor rests against the subclavian artery wall, the artery can be freed following a subadventitial plane. If there is invasion of the arterial wall, resection is necessary to obtain tumor-free margins. After proximal and distal control is obtained, the artery is divided on either side of the tumor (Fig. 21-10). Revascularization is performed using either polytetrafluoroethylene graft (6 or 8 mm) or, more often, an end-to-end primary anastomosis after freeing the carotid and subclavian arteries. During these maneuvers, the pleural space is usually opened by dividing Sibson fascia.

The middle scalene muscle is divided above its insertion on the first rib or higher, as dictated by tumor extent. This may require division of its insertions on the posterior tubercles of the transverse processes of vertebrae C2 to C7, especially for apical tumors invading the middle compartment of the thoracic inlet. The nerve roots of C8 and T1 are easily identified and dissected free from outside to inside, up to where they join to form the lower trunk of the brachial plexus. Thereafter, the ipsilateral prevertebral muscles are resected, along with the

FIGURE 21-8 ■ The subclavian artery is exposed after division of the insertion of the anterior scalenus muscle on the first rib. The phrenic nerve is protected and preserved. (Adapted from Dartevelle PG, Chapelier AR, Macchiarini P, et al: Anterior transcervical-thoracic approach for radical resection of lung tumors invading the thoracic inlet. *J Thorac Cardiovasc Surg* 105:1025, 1993.)

FIGURE 21-9 ■ Retraction of the anterior scalenus muscles allows identification of the interscalenic trunks of the brachial plexus. The subclavian artery can be gently freed from the tumor by dividing all collateral branches (the vertebral artery is generally preserved if not invaded). (Adapted from Dartevelle PG, Chapelier AR, Macchiarini P, et al: Anterior transcervical-thoracic approach for radical resection of lung tumors invading the thoracic inlet. *J Thorac Cardiovasc Surg* 105:1025, 1993.)

paravertebral sympathetic chain and stellate ganglion, from the anterior surface of the vertebral bodies of C7 and T1 (Fig. 21-11). This permits oncologic clearance of the major lymphatic vessel draining the thoracic inlet and the visualization of the intervertebral foramina. The T1 nerve root is usually divided proximally beyond visible tumor, just lateral to the T1 intervertebral foramen. Although tumor involvement of the brachial plexus may be high, neurolysis is usually achieved without division of the nerve roots above T1 (Fig. 21-12). Lateral and long thoracic nerves should be preserved to avoid winged scapula.

The chest wall resection is completed before the upper lobectomy (Fig. 21-13). The anterolateral arch of the first rib is divided at the costochondral junction. The second rib is divided at the middle arch. The third rib is scraped on the superior border toward the costovertebral angle. The specimen is progressively freed. The divided ribs are disarticulated from the transverse processes of the first two or three thoracic vertebrae. An upper lobectomy can be accomplished through this cavity, although it is technically more demanding. The additional posterior thoracotomy, as in our original description,⁶ is usually not

required. The cervical incision is closed in two layers after the sternal insertion of the sternocleidomastoid muscle is sutured. Conventional tube drainage of the ipsilateral chest cavity is carried out.

There is increasing concern about the functional and aesthetic benefit of preserving the clavicle. We believe that the indications for preserving and reconstructing the clavicle are limited to the combined resection of the serratus anterior muscle and the long thoracic nerve, because this causes the scapula to rotate and draw forward. This entity (scapula alata), combined with the resection of the internal half of the clavicle, pushes the shoulder anteriorly and medially, leading to severe cosmetic, functional discomfort. If this circumstance is anticipated, we recommend an oblique section of the manubrium that fully preserves the sternoclavicular articulation, its intra-articular disc, and the costoclavicular ligaments, rather than the simple sternoclavicular disarticulation. Clavicular osteosynthesis can be accomplished by placing metallic wires across the lateral clavicular edges and across the divided manubrium.

We developed a technique for resecting superior sulcus tumors extending into the intervertebral foramen

FIGURE 21-10 ■ If involved by the tumor, the subclavian artery can be divided after its proximal and distal control has been obtained. (Adapted from Darteville PG, Chapelier AR, Macchiarini P, et al: Anterior transcervical-thoracic approach for radical resection of lung tumors invading the thoracic inlet. *J Thorac Cardiovasc Surg* 105:1025, 1993.)

FIGURE 21-11 ■ The prevertebral muscles are extensively detached from the vertebral bodies, and both the stellate ganglion and the dorsal sympathetic chain are isolated and finally released, using raspatories, from all surrounding attachments. (Adapted from Darteville PG, Chapelier AR, Macchiarini P, et al: Anterior transcervical-thoracic approach for radical resection of lung tumors invading the thoracic inlet. *J Thorac Cardiovasc Surg* 105:1025, 1993.)

without intraspinal extension¹⁰ (Fig. 21-14). The underlying principle is the use of a combined anterior transcervical and posterior midline approach, allowing resection of the intervertebral foramen and division of the nerve roots inside the spinal canal. The procedure starts with a transcervical approach; resectability is assessed. All tumor-involved areas are resected with tumor-free margins, as described. Next, the patient is placed in a ventral position, and a median vertical incision is extended from spinal processes C7 to T4.

After a unilateral laminectomy on three levels, the nerve roots are divided inside the spinal canal at their emergence from the external sheath covering the spinal cord. The specimen is resected en bloc, with the lung, ribs, and vessels through the posterior incision (Fig. 21-15) after division of the ipsilateral hemivertebral bodies. On the side of the tumor, spinal fixation is performed from the pedicle above to the pedicle below the resected hemivertebrae. On the contralateral side, a screw is placed in each pedicle (Fig. 21-16). However, if an anterior spinal artery is discovered to be penetrating the spinal canal through an invaded intervertebral foramen, surgery is contraindicated. Tumors involving

transverse processes should be resected with the anterior approach. The maneuver is similar to that used with the posterior approach but from the front to the back, with a finger placed behind the transverse process of T1 and T2 to direct the chisel correctly (Fig. 21-17).

SURGICAL MORBIDITY AND MORTALITY

Surgical complications are numerous and vary in severity. Horner syndrome occurs after injury to the stellate ganglion. The clinical consequences are usually well tolerated. Various nerve deficits can occur as well. Although division of the T1 nerve root does not induce significant muscular palsy in the nerve distribution, resection of the lower trunk of the brachial plexus can result in atrophic paralysis of the forearm and small muscles of the hand, with paralysis of the cervical sympathetic system (Dejerine-Klumpke syndrome). This scenario should be discussed with the patient before surgery. Relief of the preoperative pain and potential cancer cure are worth

FIGURE 21-12 ■ Tumoral involvement of the brachial plexus requires an inside-out neurolysis if the upper trunks are involved, or a resection of T1 if the lower trunk or nerve roots are involved. (Adapted from Dartevielle PG, Chapelier AR, Macchiarini P, et al: Anterior transcervical-thoracic approach for radical resection of lung tumors invading the thoracic inlet. *J Thorac Cardiovasc Surg* 105:1025, 1993.)

FIGURE 21-13 ■ Once structures above the thoracic inlet are freed from the tumor, the first two ribs might be separated anteriorly at its chondrocostal junction and resected posteriorly in tumor-free margins. The third rib is scribed on its superior border toward the costovertebral angle and retracted inferiorly. (Adapted from Dartevielle PG, Chapelier AR, Macchiarini P, et al: Anterior transcervical-thoracic approach for radical resection of lung tumors invading the thoracic inlet. *J Thorac Cardiovasc Surg* 105:1025, 1993.)

the nerve sacrifice, however, and adaptation is usually reasonable.

Hemothorax can result from the extensive pleural adhesions encountered during resection, the chest wall resection, or the blood spillage from veins around the intervertebral foramina. Chylothorax should be prevented intraoperatively by extensive ligation of the cervical and intrathoracic lymphatic vessels after meticulous dissection. Whenever this occurs, continued chest tube drainage, lung expansion, or reoperation may be necessary.

Patients having a combined transcervical and midline approach are more likely than others to develop postoperative atelectasis and perfusion-ventilation mismatch. This is a result of chest wall dyskinesia and phrenic nerve resection or even temporary paresis from the dissection. Thus, these patients are unable to breathe spontaneously in the early postoperative course.

The postoperative course is characterized by atelectasis because of the extended chest wall resection, with or without phrenic nerve sacrifice. Treatment involves measures to achieve complete lung expansion by ensuring the following: ventilation (mechanical support as necessary); chest tube function; prevention of retained secretions by

FIGURE 21-14 ■ Magnetic resonance image of a right superior sulcus bronchial carcinoma extending into the intervertebral foramen (arrow) without intraspinal extension.

FIGURE 21-15 ■ Right-sided apical tumor involving the costovertebral space, intervertebral foramen, and part of the ipsilateral vertebral body. This tumor is first approached anteriorly as described in the text, and then the operation is completed through a hemivertebrectomy performed via the posterior midline approach. Arrows show the line of vertebral resection. (Adapted from Darteville PG, Chapelier AR, Macchiarini P, et al: Anterior transcervical-thoracic approach for radical resection of lung tumors invading the thoracic inlet. *J Thorac Cardiovasc Surg* 105:1025, 1993.)

FIGURE 21-17 ■ Right-sided apical tumor involving the posterior arch of the rib only and resected from the anterior cervical approach by a vertical en bloc resection of part of the lateral vertebral body, the costovertebral space, and transverse process. Arrow shows the line of vertebral resection. (Adapted from Darteville PG, Chapelier AR, Macchiarini P, et al: Anterior transcervical-thoracic approach for radical resection of lung tumors invading the thoracic inlet. *J Thorac Cardiovasc Surg* 105:1025, 1993.)

FIGURE 21-16 ■ Chest radiograph showing bilateral spinal fixation with metal rods interposed. (From Darteville PG: Extended operations for lung cancer. *Ann Thorac Surg* 63:12, 1997, with permission.)

mobilization, coughing, chest physiotherapy, and airway suctioning (even a temporary tracheostomy); optimal analgesia; and incentive spirometry.

Fluid overload should be avoided and diuretics used judiciously to avoid adult respiratory distress syndrome. Chest tubes remain in place until all air leaks have stopped and there is complete lung expansion. Fluid drainage should be minimal. Incomplete lung expansion with persistent intrapleural air space should be ignored because the space will ultimately be filled with serous fluid.

Resection of the subclavian vein should be accompanied by elevation of the ipsilateral forearm to facilitate venous drainage and generation of a collateral venous pathway (within 1 to 2 months). The radial pulse should

be followed closely to control the patency of the revascularized subclavian artery; after a preoperative loading dose of intravenous heparin, anticoagulant treatment should be switched to oral doses for a 6-month postoperative period only.

Neurologic complications are infrequent: spinal fluid leakage occurs secondary to injury to the spinal cord sheath. The risks of air embolism into the subarachnoid space, ventricles, central canal of the brain, and spinal cord space justify reoperation, during which a cerebral ventricular-venous shunt may be required.

RESULTS AND PROGNOSIS

The overall 5-year survival rates after combined radio-surgical (posterior approach) treatment of superior sulcus tumors caused by bronchial carcinoma range from 10% to 56% (Table 21-1). The best prognosis is found in patients without nodal involvement who have had a complete resection, as noted by Arcasoy and Jett¹¹ and Ginsberg and colleagues.⁵ We reported a complete resection rate of 100% with no postoperative mortality or major complications.¹² The 5-year and median survival rates were approximately 35% and 18 months, respectively. The local recurrence rate was less than 1.8% using our approach. Fadel and coworkers reported 17 en bloc resections of non-small cell lung cancers invading the thoracic inlet and intervertebral foramina, with 5-year and median survival rates of 20% and 27 months, respectively.¹³ Among the adverse prognostic factors, the nodal status is the only predictor of disease-free survival (Box 21-2). A review of our experience with superior sulcus tumors in 126 patients revealed that complete resection was achieved in 90% of cases, resulting in a median survival time of 28 months and a 5-year survival of 39.3%.¹⁴ There was one death during the study period. By multivariate analysis, incomplete resection and subclavian artery involvement adversely affected survival ($P = 0.01$,

BOX 21-2 Factors Influencing Survival and Disease-Free Survival* of Patients with Superior Sulcus Tumor†

ADVERSE PROGNOSTIC FACTORS

- Female sex
- Positive bronchoscopy
- Abnormal serum carcinoembryonic antigen (CEA)
- Full-blown Pancoast-Tobias syndrome
- Positive lymph nodes (N1-N3)

FACTORS WITHOUT PROGNOSTIC INFLUENCE

- Side and site of the tumor
- Invasion of the intervertebral foramen

*By multivariate analysis, only the nodal status adversely affected disease-free survival.

†The superior sulcus tumors had invaded the thoracic inlet, and they were completely resected through the anterior approach.

each). More recently we reviewed 54 en bloc resections of non-small cell lung cancer invading the thoracic inlet and spine.²⁷ Complete resection was achieved in 91% of cases and the 1-, 5-, and 10-year survival rates were 82%, 31%, and 31%, respectively. These results have been emphasized by an even more recent review and pooled data analysis.²⁸ Overall, these results suggest that radical surgery for superior sulcus tumors may be performed in experienced centers with low mortality and favorable survival rates.

Most primary lung cancers comprise the histologic variants described in other chapters of this text. On occasion, however, the thoracic surgeon must diagnose and treat an unusual primary lung cancer. These tumors frequently have a similar clinical presentation to more common tumors, but there are often subtle differences in treatment. Hence, knowledge of these tumors, their characteristics, and the ensuing diagnostic and treatment paradigms are important for the practicing thoracic surgeon.

BRONCHOPULMONARY CARCINOIDS

Epidemiology

Bronchopulmonary carcinoid tumors account for one quarter of all carcinoid tumors, represent 1.2% of all primary lung tumors in adults,^{1,2} and are the most common primary lung tumor in children.³ Overall, when all carcinoids are accounted for, they are distributed almost equally between males and females; however, in

the bronchopulmonary subset, they are found predominantly in females.^{4,5} The incidence is significantly higher in white patients than in black, Asian, and Hispanic patients.¹ Compared with bronchogenic carcinomas, carcinoid tumors occur more frequently in younger patients and are less likely to be associated with a significant smoking history.⁵

Bronchopulmonary carcinoid tumors arise from neuroendocrine cells and are thus positioned on the neuroendocrine tumor spectrum, which includes the more aggressive large-cell neuroendocrine carcinomas and small-cell lung carcinomas. Bronchopulmonary carcinoid tumors are classified as either typical or atypical on the basis of histologic features. Typical carcinoid tumors account for three quarters of bronchopulmonary carcinoids, are often centrally located, and rarely metastasize.⁵ In contrast, atypical carcinoid tumors are located more frequently in the lung periphery and metastasize in more than 40% of cases. Atypical carcinoid tumors occur more often with increasing age and are rarely seen in patients younger than 30 years.⁶ Unlike high-grade bronchopulmonary neuroendocrine tumors (large-cell and small-cell variants), typical and atypical bronchopulmonary carcinoids rarely occur in combination with other adenocarcinomas; however, the risk of synchronous breast and prostate cancer is slightly elevated.⁷

Pathology

Most bronchopulmonary carcinoid tumors, particularly typical carcinoids, are centrally located.⁸ Fink et al reported that 68% of bronchopulmonary carcinoid tumors were located in the major bronchi (13% in the mainstem bronchi and 55% in lobar bronchi), with the remaining 32% in peripheral locations.⁸ Because of the predominance of central location, these tumors can often be visualized bronchoscopically, demonstrating a sessile, red-brown to bluish-tan endobronchial mass with variable vascularity and a smooth surface. On gross pathologic examination, typical carcinoids appear as a white or gray cut surface without evidence of hemorrhage

or necrosis.⁹ In contrast, atypical carcinoids tend to be located peripherally in the lungs.¹⁰ On gross pathologic examination, atypical carcinoids appear white-gray on section but can exhibit a color of tan, pink to yellow-brown, and red.¹¹

The World Health Organization (WHO) classification of pulmonary neuroendocrine tumors is based on morphologic and histologic features, which clearly influence tumor behavior and prognosis.¹² The spectrum of neuroendocrine tumors includes low-grade typical carcinoids, intermediate-grade atypical carcinoids, and high-grade large- and small-cell variants. Typical carcinoid tumors have fewer than 2 mitoses per 10 high power fields (HPF), have no evidence of necrosis, and are larger than 0.5 cm. Tumors smaller than 0.5 cm are classified as carcinoid tumorlets and are addressed later in this chapter. Atypical carcinoid tumors have 2 to 10 mitoses per 10 HPF or necrosis. [Figure 22-1](#) demonstrates the histologic appearance of a typical and an atypical carcinoid tumor. In comparison, large- and small-cell carcinomas contain greater than 10 mitoses per 10 HPF and are further distinguished on the basis of other morphologic characteristics. Although the WHO classification places these four subtypes under the general heading of bronchopulmonary neuroendocrine tumors, the results of histopathologic and immunochemical studies support the idea that bronchopulmonary carcinoids are distinct from the more malignant and high-grade neuroendocrine tumors.¹³

Gustafsson and colleagues¹³ discussed a separate entity termed *diffuse idiopathic pulmonary neuroendocrine cell hyperplasia* (DIPNECH). This rare preneoplastic condition features proliferation of pulmonary neuroendocrine cells and neuroepithelial bodies. When this proliferation extends beyond the basement membrane, the group of cells is identified as a carcinoid tumorlet. These tumorlets are nodular, carcinoid-like proliferations of neuroendocrine cells less than 5 mm in size; those that proliferate to greater than 5 mm are classified as carcinoid tumors. DIPNECH can be both an adaptive response, as seen in persons living at high altitudes, and a reactive response

FIGURE 22-1 ■ **A**, H&E stain of a typical carcinoid. **B**, H&E stain of an atypical carcinoid.

TABLE 22-1 Pathologic Criteria for Carcinoid and Associated Tumors

Type of Tumor	Location	Nodal Metastases	Gross Pathologic Examination	Histologic/WHO Criteria
DIPNECH	Variable	None	Nodular bronchial wall thickening	No extension beyond basement membrane
Carcinoid tumorlet	Variable	None	Small, similar appearance to carcinoid tumors	Carcinoid-like, but <0.5 cm in size, mitoses very uncommon
Typical carcinoid	Central	Rare	White or gray with minimal evidence of necrosis or hemorrhage	<2 mitoses/2 mm ² >0.5 cm in size Lack of necrosis
Atypical carcinoid	Peripheral	Frequent	White-gray that on section appears tan, pink, red, or yellow-brown	2-10 mitoses/2 mm ² >0.5 cm in size Necrosis

DIPNECH, Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia; WHO, World Health Organization.

to lung injury, as seen in patients with obliterative bronchiolitis,¹⁴ chronic cough,¹⁵ and interstitial lung disease.¹⁶ Table 22-1 describes the major distinctions among DIPNECHs, tumorlets, and carcinoids.

Genetics and Biochemistry

Molecular genetic analysis has demonstrated that multiple genes are involved in the development and progression of carcinoid tumors. One important genetic mechanism is loss of heterozygosity (LOH), which can occur in multiple chromosomes, including but not limited to 3p, 5q21 (MCC/APC), 9p21 (*p16* gene), 11q13 (*MEN1* gene), 13q14 (retinoblastoma [*RB*] gene), and 17p13 (*p53* gene).^{17,18} LOH at chromosome 3p is the most frequent change in bronchopulmonary neuroendocrine tumors and has been observed in 40% of typical carcinoids and 73% of atypical carcinoids.¹⁸ *p53* mutations and loss of 5q21 occur in higher-grade tumors and are associated with worse survival.^{17,18}

Bronchopulmonary carcinoids are known to occur as components of familial endocrine cancer syndromes, namely multiple endocrine neoplasia 1 (MEN1), although this rarely occurs. The *MEN1* gene is inactivated by mutation in approximately 47% of typical carcinoids and 70% of atypical carcinoids.¹⁹⁻²¹ More recently, a study evaluated 129 patients with MEN1 and found that 6 of these (5%) had been diagnosed with bronchopulmonary carcinoids on initial diagnosis.²² An additional 32 patients had chest computed tomography (CT) scans for review, and 12 of these (38%) had pulmonary nodules suspicious for bronchopulmonary carcinoid, 4 of which were histologically confirmed to be a carcinoid. This study demonstrated that the incidence of bronchopulmonary carcinoid in MEN1 is much higher than previously believed; therefore, it is recommended that patients with MEN1 be screened for bronchopulmonary carcinoids with chest CT imaging every 3 years, with onset at 20 years of age.^{22,23}

The *p53* gene (chromosome 17p13) is important for maintaining genomic stability, in addition to numerous other functions. LOH or abnormal expression at the *p53* locus has been detected in 4% of typical carcinoids and 29% of atypical carcinoids.^{24,25} Kobayashi et al²⁶

BOX 22-1 Endocrinopathies Seen in Bronchopulmonary Carcinoids

Cushing syndrome
Acromegaly
Hypercalcemia
Hypoglycemia

evaluated the frequency of *p53* protein expression in several bronchopulmonary carcinoid tumors and found that the sampled typical carcinoids did not demonstrate any expression; in contrast, 20% of the sampled atypical carcinoids had expression.

Clinical Presentation

The presentation of bronchopulmonary carcinoid tumors is dependent on both the size and the location of the tumor; given the high proportion of centrally located carcinoid tumors, most patients are symptomatic at presentation. The most common symptoms are cough, hemoptysis, dyspnea, wheezing, and recurrent upper respiratory infections or pneumonia, caused by endoluminal obstruction by the tumor. Symptoms may be present for many years before diagnosis is made and almost entirely reflect the anatomic location of the lesion, as opposed to the secreted bioactive products.²⁷ Although some patients with bronchopulmonary carcinoid tumors may initially have carcinoid syndrome²⁸ (diarrhea, flushing, bronchoconstriction, and heart failure), in general this is exceedingly rare.⁸ Infrequently, bronchopulmonary carcinoids may secrete adrenocorticotrophic hormone (ACTH) (Cushing syndrome),²⁹ growth hormone,³⁰ or other bioactive substances. Carcinoid tumors are one of the most frequent causes of ectopic secretion of ACTH.³¹ Box 22-1 depicts common endocrinopathies associated with carcinoid tumors. A quarter of patients are asymptomatic,³² and thus many of these tumors are found incidentally or are never discovered. A population-based study in Denmark showed that 24% of typical carcinoids and 7% of atypical carcinoids were discovered on autopsy.²⁷

Diagnosis

Imaging

Chest radiographs (CXR) are nonspecific for bronchopulmonary carcinoids but may demonstrate an isolated, well-defined hilar or perihilar mass, occasionally with associated atelectasis or postobstructive pneumonia. Suspicious lesions should be examined further with chest CT, which is the preferred diagnostic imaging study and which allows for determination of tumor size, location, and potential lymph node involvement. On CT, carcinoids appear as well-defined, homogeneous, spherical/ovoid, endobronchial masses (Fig. 22-2) that exert mass effect or cause distal airway obstruction.³³ Spiculation is absent. Typical carcinoids are often vascular and more commonly centrally located. In contrast, atypical carcinoids are usually located peripherally, and 30% have calcifications.¹⁰

Most bronchopulmonary neuroendocrine tumors (80%) express somatostatin receptors, predominantly SST₂ receptors.³⁴ Somatostatin receptor scintigraphy (SRS) with radiolabeled somatostatin analogs (¹¹¹In-octreotide and ¹¹¹In-lanreotide) can be used to locate bronchopulmonary carcinoid tumors or metastatic lesions. However, only two thirds of these carcinoids will have positive findings on SRS, and CT is generally superior for visualizing both primary and metastatic lesions.³⁵ Furthermore, benign pathologic results can produce false-positive findings on SRS. Given these limitations and the superiority of CT scans, SRS should rarely be used in the diagnosis or workup of bronchopulmonary carcinoids.

The role of positron emission tomography (PET) in diagnosing bronchopulmonary carcinoids is not as well defined as that of either CT or SRS but has been investigated in several small, single-institution series and may benefit select patients. PET functions by detecting the accumulation of radiolabeled biological molecules (most commonly ¹⁸F-fluorodeoxyglucose [FDG]) within

neoplastic cells. Historically, the use of FDG-PET has been fraught with false-negative results in patients with solitary bronchopulmonary carcinoids, because they are often hypometabolic on FDG-PET.³⁶ More recently, however, FDG-PET, particularly when combined with CT, has shown improvement in the staging of select patients, particularly those with atypical carcinoid tumors.³⁷ Typical carcinoids generally demonstrate significantly lower average standardized uptake values (SUVs), compared with atypical carcinoids. Chong et al³⁸ reviewed FDG-PET scans of typical carcinoids ($n = 2$) and atypical carcinoids ($n = 5$) for maximum SUV. The typical carcinoids had an SUV range of 3.2 to 3.4, with both specimens exhibiting less than mediastinal uptake. Three of the five atypical carcinoids had a higher SUV (4.0 to 7.1) than the mediastinum. One of the five atypical carcinoids had a maximum SUV of 1.7, with an ipsilateral hilar lymph node measuring an SUV of 11.2.³⁸ A further potential benefit of FDG-PET is its ability to identify lymph node and distant metastases in some cases, although it does not identify these metastases in all cases.^{37,39} In summary, the role of FDG-PET is evolving, and in the future it will likely play a role in the workup of select patients, particularly those with suspected atypical carcinoid tumors. Given the possibility for false-negative results in FDG-PET scans, a lesion that is suspicious for carcinoid on CT should be treated as such.

Bronchoscopy

After the identification of an endobronchial or centrally located tumor, the next step in the diagnostic workup should be bronchoscopic evaluation. Rivera et al⁴⁰ reviewed almost 3800 patients with central, endobronchial lesions and found that the overall sensitivity of flexible fiberoptic bronchoscopy for detecting lesions was 88%. As mentioned previously, most bronchopulmonary carcinoids (75%) are centrally located and are thus amenable to bronchoscopic evaluation. Recently, electromagnetic navigational bronchoscopy (ENB) has proven to be an effective means of obtaining tissue in peripheral lesions not amenable to biopsy by standard bronchoscopic techniques. In a recent study, ENB was able to establish a diagnosis in 37 of 48 patients (77%) with such lesions who were at high risk for requiring more invasive procedures.⁴¹ On bronchoscopic evaluation, carcinoid tumors are often smooth with a distinct reddish-brown appearance. Biopsy should be performed in an effort to establish a diagnosis, although distinguishing typical from atypical carcinoids can sometimes be challenging because of the small tissue sample typically obtained with flexible bronchoscopy.⁴² Given this difficulty and the fact that 5% to 20% of typical carcinoids and 30% to 70% of atypical carcinoids metastasize to regional lymph nodes, lymphadenectomy at the time of surgery should be strongly considered for accurate staging.¹¹ Additionally, there are several cases in the literature of carcinoid tumors overdiagnosed as small-cell carcinomas on the basis of bronchoscopic biopsies.⁴³ An accurate diagnosis is best achieved by careful evaluation of hematoxylin and eosin sections and mitotic index, as treatments differ radically among these separate entities.

FIGURE 22-2 ■ Chest CT scan of a typical carcinoid.

In the past, a feared complication of bronchoscopic biopsy of carcinoid tumors was major hemorrhage; however, several more recent studies have shown this to be a rare occurrence, and biopsy is considered a safe venture. In a review of 587 biopsies by flexible and rigid bronchoscopy, there was significant hemorrhage in 15 patients (2.6%), with only 4 (0.7%) requiring emergency intervention secondary to massive uncontrollable hemorrhage.⁴⁴ Mucosal injection of an epinephrine solution before biopsy can mitigate some of the risk of hemorrhage. In the event of significant bleeding that is difficult to control, a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser is helpful.^{45,46} If standard bronchoscopic and ENB biopsy techniques are unable to successfully biopsy peripheral tumors, CT-guided percutaneous transthoracic needle biopsy, video-assisted thoracic surgery, and thoracotomy are other options.

Tumor Markers

Serotonin and urinary 5-HIAA are well-known markers of hormonally active carcinoid tumors; however, they are not specific for bronchopulmonary carcinoids. Chromogranin A (CgA) elevation in plasma is a relatively sensitive (75%) marker of bronchopulmonary carcinoids.⁴⁷ Care must be taken in patients with renal impairment and atrophic gastritis and during proton pump inhibitor therapy, because these conditions cause elevations in CgA and thus false-positive results. In clinical practice, there is no evidence that measurement of tumor marker levels adds value or alters patient management; therefore, it is not routinely performed.

Staging

The TNM (tumor, nodes, metastasis) classification for lung cancer remains the most widely used staging classification for bronchopulmonary carcinoid tumors.⁴⁸ Fink et al analyzed 142 bronchopulmonary carcinoids, of which 128 were typical and 14 were atypical. Lymph node metastases were less common in the subset of typical carcinoids (N0 = 87%, N1 = 10%, N2 = 3%), compared with atypical carcinoids (N0 = 43% N1 = 29%, N2 = 14%, N3 = 14%). As for other histologic variants of lung cancer, for bronchopulmonary carcinoids, N1 disease is defined as ipsilateral hilar lymph node involvement, N2 disease is defined as ipsilateral mediastinal lymph node involvement, and N3 disease is defined as contralateral or distant nodal involvement. None of the patients with typical carcinoid was found to exhibit N3 disease. Distant metastatic disease (M1) was found in 2% of typical and 21% of atypical carcinoid tumors.⁸

A larger, more recent Italian study⁴⁹ retrospectively analyzed 252 patients, 174 with typical and 78 with atypical carcinoid tumors, during a 38-year period and found that 96% of patients with typical carcinoids presented without nodal metastases, 3.4% presented with N1 disease, and 0.6% presented with N2 disease. In contrast, only 72% of patients with atypical carcinoids presented without nodal metastases, 17% presented with N1 disease, and 11% presented with N2 disease. Thus, typical carcinoids rarely have nodal disease, whereas

atypical carcinoids commonly have either N1 or N2 disease—again highlighting the different tumor biology between these two tumors. The two previously mentioned studies and others are summarized in Table 22-2.

Management and Treatment

Surgery

Complete surgical resection with preservation of normal lung tissue remains the only curative treatment of bronchopulmonary carcinoids.¹³ When considering bronchopulmonary carcinoid tumors, there should be three surgical goals: (1) complete resection of the tumor (R0 resection), (2) sparing of the parenchyma whenever possible, and (3) lymph node staging by either ipsilateral lymph node sampling or mediastinal lymph node dissection.

Centrally located typical carcinoids should be resected using lung parenchyma-sparing resections, such as sleeve resection, or anatomic segmentectomy.⁵⁰⁻⁵¹ Because local recurrence is rare, surgical treatment of typical carcinoids does not require a wide margin of resection.⁴⁹ Ferguson and coworkers, in a multicenter retrospective study, found that wide nonanatomic wedge resection or segmentectomy was justified in the case of peripheral typical carcinoid tumors because of the low likelihood of local recurrence.⁵² Additionally, sleeve bronchial resections without parenchymal resection have been described for select patients with typical carcinoid tumors who have no evidence of nodal metastasis.⁵³

Although most agree that nonanatomic resection, when possible, is acceptable for the management of typical carcinoids, the surgical approach for atypical carcinoids is typically lobectomy or, rarely, pneumonectomy. When sleeve lobectomy is a reasonable alternative to pneumonectomy, this approach is preferred.⁵⁴ Given the greater propensity of atypical carcinoids to metastasize to lymph nodes, a more extensive and aggressive resection (lobectomy, bilobectomy, and pneumonectomy) and nodal dissection are recommended.⁵⁵⁻⁵⁷

Surgical resection of bronchopulmonary carcinoids should be combined with ipsilateral mediastinal lymph node dissection or sampling.⁴⁹ The necessity of lymph node dissection is justified by the possibility of lymph node metastasis, which has an incidence of 4% to 13% in typical carcinoids and 28% to 67% in atypical carcinoids.^{8,49,50,58}

Endobronchial Management

Endobronchial intervention using Nd:YAG laser removal or mechanical tumor removal has been described in highly selected patients with intraluminal typical carcinoid tumors, with excellent local control and low rates of recurrence.⁵⁹ Bertoletti and colleagues⁶⁰ conducted a study of 18 patients (all with typical carcinoid, strict endoluminal disease, and no evidence of lymph node invasion) treated with flexible bronchoscopy and cryotherapy. Patients were monitored for 55 months; there was one recurrence in 7 years, with no long-term complications. Finally, in a recent retrospective review, 25

BP, Bronchopulmonary.

endoscopically treated patients were compared with 48 patients who underwent surgical resection, and there was no difference in mortality.⁶¹ No recurrences were noted in either group. Although these results are encouraging, the current standard of care is surgical resection, and endobronchial resection should be reserved for patients who are not candidates for surgical intervention because of medical risk factors.

Adjuvant Therapies: Radiation, Chemotherapy, and Targeted Therapy

Bronchopulmonary carcinoids respond poorly to radiotherapy, and this treatment modality is generally reserved for use when surgical resection is impractical or as an adjunct when resection is incomplete.^{13,62}

There is no role for adjuvant chemotherapy following resection of a typical carcinoid tumor, regardless of lymph node status. In patients with atypical carcinoids, chemotherapy can be used as an adjunct, but response rates are typically low.⁶³ The recommendations for adjuvant doublet, platinum-based chemotherapy are largely based on similar indications for other non-small cell lung cancer (NSCLC) histologic profiles and the presence of N1 or N2 disease. No clinical trials to date have specifically addressed the role, agent, or dosing regimen for atypical carcinoids.

Whereas cytotoxic chemotherapy regimens have had limited success, more recent evidence suggests that targeted therapies against mammalian target of rapamycin,^{64,65} vascular endothelial growth factor,⁶⁶ and platelet-derived growth factor⁶⁷ may be efficacious, although more clinical data are needed.

Prognosis

With an increase in the number of chest imaging studies performed, as well as the enhanced quality of the imaging techniques, there has been an increase in the incidence of bronchopulmonary carcinoids. Despite what could be perceived as earlier detection of all carcinoid tumors, a review of the SEER database demonstrated a decrease in the 5-year survival of patients with all carcinoids (including atypical ones) during the past 30 years.² Reasons for this decrease in survival are unclear but may be related to an increase in the incidence of the atypical carcinoid histologic profile.

It is well known that typical carcinoids have a superior prognosis, compared with atypical carcinoids. This difference is primarily attributable to the differences in tumor biology between the two histologic profiles. Recent studies have shown the 5-year and 10-year survival rates for patients with typical carcinoids to be 89% to 99% and 82% to 93%, respectively. In contrast, the 5-year and 10-year survival rates for patients with atypical carcinoids are 70% to 77% and 52% to 67%, respectively.^{8,49,50,58}

The prognostic significance of lymph node involvement in atypical carcinoid tumors cannot be overstated and has been addressed by multiple studies (see [Table 22-2](#)). The 5-year survival for atypical carcinoids with node-positive disease is 59% to 60%, compared with 83% to 100% for node-negative disease. For typical

carcinoids, however, the presence or absence of nodal disease does not correlate with survival.^{58,68}

CARCINOID TUMORLETS

Epidemiology

A carcinoid tumorlet is a nodular proliferation of pulmonary neuroendocrine cells that extends beyond the basement membrane but is less than 5 mm in size; those that proliferate to greater than 5 mm are classified as carcinoid tumors.¹³ Carcinoid tumorlets and carcinoid tumors have long been associated in the literature, but a definitive relationship has not been firmly established. Studies have demonstrated the presence of tumorlets in normal lungs or in association with carcinoid tumors.^{69,70} There have also been case reports of isolated peribronchial⁷¹ and hilar⁷² lymph node metastases, which point to the possible neoplastic potential of carcinoid tumorlets. In each of these circumstances, the lymph nodes appeared normal on gross examination; however, on pathologic examination, microscopic metastases were found.

Pathology

Carcinoid tumorlets develop from Kulchitsky cells, which are hyperplastic neuroendocrine cells in the bronchial and bronchiolar mucosa. Tumorlets can be single or multiple, are less than 5 mm in size, and have a carcinoid-like appearance. It has been suggested that these cells secrete neuropeptides that can elicit peribronchiolar reaction, leading to fibrotic lung disease.^{14,73,74}

Clinical Presentation and Diagnosis

Most pulmonary carcinoid tumorlets are asymptomatic and thus are discovered incidentally, even if multiple tumorlets are present. Pulmonary symptoms, dysfunction, and radiologic abnormalities have occasionally been attributed to multiple tumorlets.⁷⁵ In a retrospective review of 28 patients, those with multiple nodules were most likely to present with cough (59%) and dyspnea (47%); however, 41% of patients had no symptoms at presentation. Almost half of the patients (47%) with multiple nodules were nonsmokers, but 59% demonstrated obstructive patterns on pulmonary function testing.⁷⁵

Management and Treatment

There is no consensus on the management of carcinoid tumorlets. If, on pathologic examination, a carcinoid tumorlet is discovered at the resection margin, further surgical resection is not advocated. In cases where carcinoid tumorlets are associated with bronchopulmonary carcinoids, the appropriate management and treatment are dictated by the histologic profile and stage of the carcinoid tumor. Clinical surveillance may be indicated for patients with carcinoid tumorlets, because they are believed by some to progress, in rare cases, to a true carcinoid tumor; the evidence for this, however, is conflicting.⁷⁶⁻⁷⁸

Prognosis

The risk of progression to carcinoid tumor, although unproven, is at least uncommon, and although there are reports in the literature of metastatic progression,^{71,72} this is an exceedingly rare event. There is a small risk of fibrotic lung disease secondary to carcinoid tumorlets. One study demonstrated that, when tumorlets occur in conjunction with true carcinoid tumors, the multicentricity may confer a poorer prognosis.⁷⁹ Most patients with tumorlets will have persistent and stable disease without the need for additional therapy.

PRIMARY PULMONARY SALIVARY GLAND-TYPE NEOPLASMS

Epidemiology

Primary salivary gland-type lung tumors are rare, low-grade, intrathoracic malignancies, and they account for 0.2% of all lung tumors.⁸⁰ These tumors include adenoid cystic carcinomas (ACCs), mucoepidermoid carcinomas (MECs), and mixed tumors (ACC and MEC)⁸¹ (Table 22-3). It has been postulated that these tumors arise from the submucosal glands of the tracheobronchial tree and are probably related to structural homology between exocrine glands.^{81,82}

Molina et al performed a retrospective review of 62 patients with primary salivary gland-type lung cancer and found that ACC was the most frequent histologic profile (64.5% of patients), followed by MEC (32.3%) and mixed tumor (3.2%).⁸³ These results are largely consistent with those of previous series, although in some series MEC is reported to be the most frequent histologic form. Patients diagnosed with ACC generally have more advanced age than those with MEC (54 vs. 40 years; $P = 0.02$) and are more likely to have a history of smoking or to currently smoke.⁸³

Pathology

On bronchoscopic or gross evaluation, MECs will often have a smooth appearance and are typically pink, gray, or tan in color. In contrast, ACCs are typically exophytic, have less defined borders, and may ulcerate or infiltrate surrounding tissue. On histologic examination, MECs demonstrate mucous cells in conjunction with varied proportions of epidermoid, clear, and "intermediate" cells.⁸³

Several staging systems have been described for MECs, with the Brandwein⁸⁴ and the Armed Forces Institute of Pathology (AFIP)⁸⁵ systems being two of the more commonly used options. The Brandwein system is a three-stage grading system (low, intermediate, and high) that assigns points for different histologic features. Two points are assigned for an intracystic component (<25%), invasion in small nests or islands, or nuclear atypia. Three points are assigned if there is lymphatic/vascular invasion, bony invasion, greater than 4 mitoses per 10 HPF, perineural spread, or necrosis. Summation of these points grades the MEC as low (0 points), intermediate (2-3 points), or high grade (4-21 points).⁸⁴ Similarly, the AFIP system is a points-based system: 2 points are given for intracystic components or neural invasion, 3 points are given for necrosis or greater than 4 mitoses per 10 HPF, and 4 points are given for anaplasia. Once again, the points are summed, and tumors are categorized as low (0-4 points), intermediate (5-6 points), or high grade (7-14 points).⁸⁵ Table 22-4 summarizes these grading systems.

ACC tumors exhibit myoepithelial cells with various degrees of ductal type cells and are graded on the basis of their predominant architectural pattern. According to the Perzin⁸⁶ and Szanto⁸⁷ grading systems, grade 1 tumors are predominantly tubular without a solid component, grade 2 tumors are predominantly cribriform with less than 30% solid component, and grade 3 tumors have greater than 30% solid component. The other commonly used staging system, discussed by Spiro et al,⁸⁸ describes grade 1 tumors as mostly tubular or cribriform with only minor solid components, grade 2 tumors as having 50% solid component, and grade 3 tumors as mostly solid. Table 22-5 summarizes the grading systems for ACCs.

Clinical Presentation

Most salivary gland tumors are endobronchial lesions that arise centrally within large airways, although primary peripheral ACC of the lung has rarely been reported.^{81,89} Symptoms are typically related to the sequelae of either endoluminal obstruction or extraluminal compression secondary to the central tumor location.

Molina et al retrospectively reviewed 49 patients with MEC and 115 patients with ACC and found the most common symptoms to be cough, dyspnea, hemoptysis, wheezing, and fever. Dyspnea (60% vs. 35%) and wheezing (42.5% vs. 30%) were more common in ACC patients than MEC patients.⁸³

TABLE 22-3 Primary Pulmonary Salivary Gland-Type Tumors

Tumor Type	Location	Pathologic Profile	Sputum Cytologic Result	Treatment
ACC	Trachea, bronchi, lung	Myoepithelial cells, ductal type cells	Negative	Surgery, radiation therapy
MEC	Bronchi	Mucus cells, epidermoid cells, clear-type cells, "intermediate" cells	Negative	Surgery
Mixed tumor	Trachea, bronchi	Mix of ACC and MEC	Negative	Surgery

ACC, Adenoid cystic carcinoma; MEC, mucoepidermoid carcinoma.

TABLE 22-4 Grading Systems for Pulmonary Mucoepidermoid Carcinomas

	Brandwein et al ⁸⁴	AFIP ⁸⁵
Variables	Intracystic component <25% (2 points) Invasion in small nests/islands (2 points) Nuclear atypia (2 points) Lymphatic/vascular invasion (3 points) Bony invasion (3 points) >4 mitoses/10 HPF (3 points) Perineural spread (3 points) Necrosis (3 points)	Intracystic component (2 points) Neural invasion (2 points) Necrosis (3 points) >4 mitoses/10 HPF (3 points) Anaplasia (4 points)
Grading	Low grade: 0 points Intermediate grade: 2-3 points High grade: 4 or more points	Low grade: 0-4 points Intermediate grade: 5-6 points High grade: 7-14 points

TABLE 22-5 Grading Systems for Adenoid Cystic Carcinomas

Grade Number	Perzin et al ⁸⁶ and Szanto et al ⁸⁷	Spiro, Huvos ⁸⁸
Grade 1 (Low)	Predominantly tubular, no solid component	Mostly tubular or cribriform, minor solid components
Grade 2 (Intermediate)	Predominantly cribriform, <30% solid component	50% solid component
Grade 3 (High)	Solid component >30%	Mostly solid

Diagnosis

CXRs will most likely appear normal, unless the tumor obstructs the airway. The imaging study of choice is chest CT, which is recommended to obtain more detail about both the intraluminal and the extraluminal extent of ACCs and MECs.⁹⁰ Given the predominance of centrally located primary salivary gland-type lung tumors, flexible bronchoscopy is the primary diagnostic modality because it offers opportunities for direct visualization and tissue diagnosis.

Management and Treatment

Surgery

Complete surgical resection remains the only curative treatment of ACCs and MECs and should be performed with parenchyma-sparing techniques when possible. Given the propensity for ACCs to spread submucosally and perineurally, intraoperative frozen sections should be

used to confirm negative margins.⁹¹ It should be noted, however, that ACCs have a propensity to extend longitudinally in a perineural manner, and in some cases a microscopically negative surgical margin may not be obtainable. In these cases, the surgeon should resist the temptation to resect further, if additional resection would jeopardize a successful tracheobronchial anastomosis.⁹² A recent review of patients with primary salivary gland-type lung tumors revealed the most commonly performed resections were lobectomy (44%), tracheal resection (26%), and pneumonectomy (19%).⁸³ To spare lung parenchyma, sleeve resection should be considered when feasible.⁹³ Because of the high recurrence rate (23-27%) of these tumors,^{93,94} an R0 resection, when possible, should be the goal. For patients who experience recurrence, repeat resection results in good outcomes and excellent long-term survival.⁹³

Endobronchial Treatment Strategies

Brutinel et al compiled a 2-year experience with endobronchial Nd:YAG laser therapy to relieve endobronchial obstruction. Of the 116 patients in the study, 8 had ACC. When these patients were treated with laser therapy for palliation, they remained asymptomatic for longer periods, compared with those with more common forms of lung cancer.⁹⁵ Endobronchial laser therapy should precede radiation therapy if possible, because edema from radiation therapy may temporarily exacerbate the airway obstruction.^{96,97} Endobronchial brachytherapy can be used for recurrent ACC, with good palliative results.⁹⁸

Adjuvant Treatment

ACCs are relatively radiosensitive; the role of radiation therapy for MEC is more controversial. The likelihood of achieving a complete response for ACC correlates significantly with a dose of ≥ 60 Gy.⁹⁹ The role of radiation therapy for patients with ACC is most often in the adjuvant setting, particularly for those with positive resection margins at the time of surgery or for palliation.⁸³ However, there have been reports of using radiation as the primary treatment for ACC, with complete clinical response and long-term disease-free survival.^{100,101} It is generally recommended to use adjuvant radiation for centrally located ACC lesions, regardless of whether the resection is R₀, R₁, or R₂.¹⁰²

The role of chemotherapy is not well defined for ACC or MEC, but chemotherapy may be considered in cases of metastatic ACC. Hotte et al conducted a phase II consortium study to assess the antitumor activity of imatinib (Gleevec) in ACCs, which are known to express a high level of *c-kit*. Of the 16 patients enrolled in the study, 15 had an assessable response. After two cycles, 9 patients had stable disease, and 6 had progressive disease. Therefore, there is no role for routine administration of imatinib in the treatment of patients with ACC.¹⁰³

Prognosis

Patients with primary salivary gland-type lung tumors have significantly better outcomes than those with

FIGURE 22-3 ■ Kaplan-Meier survival curve for MEC versus ACC. (From Molina JR, Aubry MC, Lewis JE, et al: Primary salivary gland-type lung cancer: spectrum of clinical presentation, histopathologic and prognostic factors. *Cancer* 110:2253–2259, 2007.)

NSCLCs, because these lung tumors are considered low-grade malignancies. Five- and 10-year survival rates for ACC have been reported to be 55% to 79% and 39% to 57%, respectively,^{83,94} compared with 88% and 88% for MEC.^{83,94} Figure 22-3 shows the survival curves for patients with MEC and ACC.

Tumor grade is both a prognostic marker and a factor in determining adjuvant therapy for MEC.¹⁰⁴ Yousem and Hochholzer reported a 95% survival rate for patients with low-grade MEC tumors and found that almost 25% of patients with high-grade MEC tumors experienced recurrences.¹⁰⁴ The rate of nodal metastases is related to tumor grade, with 2% of low-grade and 15% of high-grade MEC tumors presenting with regional lymph node metastases.⁸²

PRIMARY PULMONARY SARCOMAS

Primary pulmonary sarcomas are rare neoplasms accounting for only 1% of lung cancers. They must be distinguished from the more common sarcomas metastatic to the lung, primary pulmonary sarcomatoid carcinomas, and diffuse malignant mesotheliomas involving the lung.^{105,106} An accurate history of the patient is important, particularly confirming the absence of a personal history of cancer. The history and physical examination should also focus on a search for occult neoplasm. Ultimately, however, a tissue biopsy is paramount to making an accurate diagnosis.

Historically, the distinction in the literature between true sarcomas and carcinomas with sarcomatous components has been somewhat cloudy, which makes the older literature challenging to interpret. In 2004, the WHO, in an effort to better define these distinctions, updated the classifications of primary pulmonary sarcomas and similar lesions. The WHO identified a distinct group of poorly differentiated non-small cell carcinomas that contain sarcoma or sarcoma-like components and labeled these “sarcomatoid carcinomas.” There are five distinct subgroups in the 2004 WHO classification of sarcomatoid carcinomas: pleomorphic carcinoma, spindle cell

FIGURE 22-4 ■ Histologic slide of a leiomyosarcoma.

carcinoma, giant cell carcinoma, carcinosarcoma, and pulmonary blastoma.¹⁰⁵ The primary pulmonary sarcomas described in the subsequent subsections have maintained their own classification and presence in the current literature.

Primary Pulmonary Leiomyosarcoma

Primary pulmonary leiomyosarcomas can arise in several areas of the lung, including the pulmonary artery (10%), the bronchus (20%), and the pulmonary parenchyma (70%).¹⁰⁷ A review of 18 patients with primary leiomyosarcomas of the lung showed a mean age of 50 years (range, 5 to 76 years).¹⁰⁸ Most of the patients were asymptomatic on presentation, with the neoplasms discovered incidentally. On gross pathologic examination, these lesions are well circumscribed, grayish-white, firm, and rubbery.¹⁰⁸ A typical histologic appearance is shown in Figure 22-4. Moran et al classified these lesions as low, intermediate, or high grade based on cytologic findings. Low-grade tumors showed an orderly proliferation of spindle cells, minimal pleomorphism, and few mitoses without hemorrhage or necrosis. Intermediate-grade lesions maintained the orderly proliferative pattern but had increased cellular atypia, occasional pleomorphism, and a higher mitotic index. High-grade lesions were highly cellular with marked pleomorphism and atypia, high mitotic index, and areas of hemorrhage and necrosis.¹⁰⁸ Radiographically, pulmonary leiomyosarcomas are usually well-demarcated, smooth, or lobular masses that may exhibit intratumoral hemorrhage or necrosis^{109,110} (Fig. 22-5).

Given the rarity of primary pulmonary leiomyosarcomas, there is little consensus on treatment. The most commonly accepted therapy is radical surgical excision, as is the case for other pulmonary sarcomas.¹¹¹ There is a lack of evidence for the effectiveness of radiation and chemotherapy in the treatment of primary pulmonary leiomyosarcomas; however, doxorubicin and ifosfamide are considered the most effective agents for soft-tissue sarcomas.¹¹² Grade is one of the most important prognostic indicators. In one study, high-grade lesions had

FIGURE 22-5 ■ Chest CT scan of a large primary pulmonary leiomyosarcoma. (From Gladish GW, Sabloff BM, Munden RF, et al: Primary thoracic sarcomas. *Radiographics* 22:621–637, 2002.)

significantly poorer prognosis (8 of 9 patients [89%] died within 2 years of diagnosis), compared with low- or intermediate-grade lesions (all 6 patients were alive at the end of the study period; mean follow-up, 6 years).¹⁰⁸

Primary Pulmonary Synovial Sarcoma

Primary pulmonary synovial sarcoma is a mesenchymal spindle cell tumor that accounts for 0.5% of all lung malignancies. Tumors may arise from the lung parenchyma, the bronchial tree, or the pulmonary arteries.¹¹³ Most pulmonary tumors are peripheral, with occasional endobronchial lesions.^{114,115} The median age of patients at diagnosis is 40 years, and there is no significant difference between men and women.^{116,117} On gross pathologic examination, the tumors are soft, tan masses often with foci of necrosis, hemorrhage, and cystic changes, and they are histologically indistinguishable from other soft-tissue synovial sarcomas.¹⁰⁸ Molecular testing for a characteristic t(X;18) chromosomal translocation, present in 90% of these tumors, confirms the diagnosis.¹¹⁵ Additionally, the presence of two embryonic tumor markers, epithelial membrane antigen and vimentin, may help differentiate primary pulmonary synovial sarcomas from other lesions.¹¹³

Similar to patients with other pulmonary sarcomas, most patients with pulmonary synovial sarcoma are asymptomatic at presentation. When symptoms are present, cough (21%), chest pain (20%), and hemoptysis (20%) are the most common.¹¹³ Metastatic synovial sarcoma to the lungs is more common than its primary counterpart; therefore, metastatic disease must be ruled out before therapy. The standardized therapy for patients with primary pulmonary synovial sarcoma is surgical resection and adjuvant radiation or chemotherapy, depending on the findings at the time of surgery. Synovial sarcoma is chemosensitive to doxorubicin and ifosfamide,

with an overall response rate of 24%.¹¹⁸ Tumors tend to recur locally, with extension into the chest wall, pericardium, paraspinal soft tissue, diaphragm, and abdomen.¹⁰⁵ The overall prognosis for patients with primary pulmonary synovial sarcoma is poor, with an overall 5-year survival rate of 50%.¹¹⁹ Risk factors that predict a poorer prognosis for patients with primary pulmonary synovial sarcoma are age 20 years and older, tumor size greater than 5 cm, incomplete resection, and large number of mitotic figures.¹¹³

Primary Pulmonary Epithelioid Hemangioendothelioma

Pulmonary epithelioid hemangioendothelioma, previously referred to as intravascular bronchioloalveolar tumor, is a primary pulmonary sarcoma that is considered a low- to intermediate-grade vascular tumor. Pulmonary epithelioid hemangioendothelioma affects young patients and is more common in women than in men.¹²⁰ On gross pathologic examination, the tumor is gray-white or gray-tan in appearance. The cut surface is of cartilaginous consistency with occasional calcification. Histologically, the tumor has a distinctive appearance, with short cords and nests of epithelioid cells associated with a myxohyaline matrix.¹⁰⁵

Preoperative diagnosis remains difficult, and most diagnoses are made from pathologic evaluation of surgical biopsy specimens. Immunohistochemical analysis shows diffuse cytoplasmic staining of the malignant cells with factor VIII-related antigen, confirming the lineage of tumor cells.¹²⁰ Half of patients present with nonspecific respiratory symptoms similar to those of other lung neoplasms (cough, dyspnea, or chest pain). Imaging often demonstrates the presence of multiple bilateral nodules with occasional calcification.^{121–124}

Because primary pulmonary epithelioid hemangioendothelioma is rare, few data exist regarding a standard treatment strategy. In patients with a unilateral nodule, wedge resection seems to offer similar survival benefits to anatomic resection.¹²⁰ The prognostic value of lymph node sampling is unknown because of the small number of patients who demonstrate lymph node metastases.¹²⁵ Patients with bilateral nodules have undergone a variety of treatments, ranging from interferon alfa-2a¹²⁶ to azathioprine¹²⁷ to multiple wedge resections¹²⁸ to no treatment. Bagan and colleagues endorse the consideration of lung transplantation for patients with vascular aggressiveness and pleural hemorrhagic effusion because these patients have a life expectancy of less than 1 year.¹²⁰

Prognosis is, in part, dependent on sites of metastases; however, unlike for other lung cancers, for pulmonary epithelioid hemangioendothelioma, simultaneous lesions in the lung and the liver do not necessarily mean metastases. Epithelioid hemangioendothelioma may also be found as a second concurrent primary in the liver. This is important in the transplant community because surgeons who manage transplantation for hepatic hemangioendothelioma do not consider a focal lesion in the lung to be a metastasis.¹²⁹ Bagan et al indicate that the current staging system for lung cancer does not predict outcomes for primary pulmonary epithelioid

hemangioendothelioma, and they advocate the use of clinical and radiologic disease to guide prognosis.¹²⁰ Prognosis in patients with primary pulmonary epithelioid hemangioendothelioma can be sorted into two groups: (1) asymptomatic patients with nodules, who have a median survival of 180 months, and (2) patients with symptoms of vascular endothelial cell proliferation (alveolar hemorrhage, hemoptysis, hemorrhagic pleural effusion), who have a significantly worse survival of generally less than 1 year.¹²⁰

Primary Pulmonary Angiosarcoma

Malignant vascular tumors are highly uncommon, with angiosarcomas constituting less than 1% of all sarcomas.¹³⁰ Pulmonary angiosarcomas are usually the consequence of metastasis from the skin or subcutaneous tissue, breast, liver, or heart. Primary pulmonary angiosarcoma is characterized by an insidious growth pattern, with the tumor showing extensive local invasion and hematogenous metastases at the time of presentation.¹³¹ Demographically, angiosarcomas typically arise in middle-aged adults. These tumors have been tied to radiation therapy and to exposure to vinyl chloride and arsenic.¹³²

Histologically, these lesions can mimic carcinomas and exhibit cytokeratin positivity.¹³³ Some patients may have bilateral infiltrates that mask pulmonary hemorrhage. The most common clinical characteristic at presentation is hemoptysis.¹³³ Radiographically, these lesions usually present as multiple bilateral nodules.¹³⁴

Surgery remains the mainstay treatment for primary pulmonary angiosarcomas, with radical resection the preferred choice. Angiosarcomas are radiosensitive. Paclitaxel, which exerts antiangiogenic and apoptotic effects, has been shown to be effective against angiosarcoma.¹³⁵ The prognosis of patients with angiosarcomas is quite poor, with most patients dying within months of initial presentation.¹³⁰

PRIMARY SOLITARY PULMONARY PLASMACYTOMA

Epidemiology and Pathology

Extramedullary plasmacytomas are uncommon neoplasms of plasma cell origin. Most of these tumors arise in the head and neck region; in rare occurrences they may arise in the lung as a solitary nodule or less commonly as a lobar consolidation or as diffuse pulmonary infiltrates.¹³⁶ Joseph and colleagues evaluated 19 cases of primary pulmonary plasmacytoma and found that males and females were affected equally and that the median age at diagnosis was 42 years.¹³⁷

Clinical Presentation and Diagnosis

Patients are either asymptomatic on presentation or have nonspecific pulmonary symptoms of cough, wheeze, or shortness of breath.¹³⁶ Diagnosis of primary pulmonary plasmacytoma is difficult. The clinician should undertake the workup of a lung nodule or mass, including CT scan.

Most commonly, the diagnosis is made after excision of the tumor and proper histopathologic examination.

Treatment and Prognosis

Treatment for primary pulmonary plasmacytomas is usually resection alone or a combination of surgery and chemotherapy or radiotherapy. A review of 19 patients with primary pulmonary plasmacytomas found that a variety of treatment modalities had been used: surgery alone ($n = 11$), radiation therapy ($n = 3$), surgery with radiation ($n = 3$), and surgery with chemotherapy ($n = 2$). The authors concluded that surgery and radiotherapy are both effective treatments with low rates of local recurrence.¹³⁷ Solitary pulmonary plasmacytoma has been shown to occasionally progress to multiple myeloma over time.^{138,139} Thus, once the diagnosis is made, it is essential that a complete evaluation be performed, to exclude systemic disease. After resection, patients should be monitored closely by use of serum and urine electrophoresis, skeletal bone survey, and bone marrow examination.¹³⁶

PRIMARY PULMONARY LYMPHOMA

Epidemiology

Primary pulmonary lymphomas are uncommon, representing less than 1% of lung cancers¹⁴⁰ and less than 1% of malignant lymphomas¹⁴¹ and accounting for only 3.6% of extranodal lymphomas.¹⁴² The peak incidence of primary pulmonary lymphomas is in the sixth and seventh decades of life, with an equal distribution between men and women.¹⁴³ It has been well documented that immunosuppression is a risk factor for the development of lymphoma.¹⁴⁴

Pathology

The vast majority of primary pulmonary lymphomas are of B cell origin. One study of 62 cases of primary pulmonary lymphoma demonstrated 58 B cell cases, 2 T cell cases, and 2 indeterminate cases.¹⁴³ B cell mucosal-associated lymphoid tissue (MALT) lymphomas are the predominant tumor type. Most MALT lymphomas are low grade, but transition to higher grade can occur in a minority of cases.¹⁴⁵

Clinical Presentation and Diagnosis

Graham and coworkers¹⁴⁵ reported a series of 18 patients with primary pulmonary lymphoma. The most common pulmonary symptoms at presentation were cough (50%), dyspnea (39%), and chest pain (17%). Additionally, some patients suffered from systemic symptoms of fatigue (11%) and weight loss (6%). Twenty-two percent of patients were asymptomatic at presentation.

Management and Treatment

Once diagnosed, the primary pulmonary lymphoma must be appropriately staged to rule out extrathoracic

disease. This includes additional imaging, possible bone marrow biopsy, and laboratory tests (lactate dehydrogenase and β_2 -microglobulin).^{146,147} In the case of an isolated primary pulmonary MALT lymphoma diagnosed by CT-guided biopsy, management is observation only, reserving treatment for possible future progression of disease on the basis of symptoms and radiographic progression. In cases where the diagnosis was established after wedge resection or lobectomy with negative margins and no evidence of high-grade transformation or disease elsewhere, a complete resection is considered definitive, and no further therapy is required. If there is residual disease, disease in the contralateral chest, high-grade lymphoma, or extrathoracic disease, then chemotherapy and, rarely, radiation should be considered.¹⁴⁵

Prognosis

Cordier et al¹⁴⁸ reported a 5-year survival of 94% for low-grade primary pulmonary lymphoma and a median survival of 3 years for high-grade disease. Ferraro et al¹⁴⁹ reported a 5-year survival of 68% for primary pulmonary MALT lymphoma.

PRIMARY PULMONARY MELANOMA

Epidemiology

Primary pulmonary melanomas are among the rarest of primary lung tumors: only a few dozen cases have been reported in the English-language literature.^{150,151} Because of the scarcity of these tumors, their clinical presentation, natural history, treatment, and prognosis are not well defined.

Pathology

Making a diagnosis of primary pulmonary melanoma and distinguishing it from the much more common metastatic melanoma is not an easy task. Authors have suggested that several criteria should be required for a diagnosis of a primary pulmonary tumor.¹⁵²⁻¹⁵⁴ These include (1) "nesting" of melanoma cells beneath the bronchial epithelium; (2) invasion of melanoma cells into the bronchial epithelium; (3) solitary lung tumor; (4) lack of a personal history of cutaneous, mucosal, or ocular melanoma; and (5) negative findings from a thorough search for occult melanoma. Even so, there is still some controversy about whether this lesion is a primary pulmonary lesion. At the heart of the controversy is the belief that, to have a primary pulmonary melanoma there must be a melanin-containing precursor cell. However, melanin-containing cells have not been demonstrated in the normal tracheobronchial tree.¹⁵⁰ Despite this, it has been postulated that, because the trachea shares an embryologic origin with the pharynx and esophagus, both of which are known to give rise to primary melanomas, the primary pulmonary melanoma is a consequence of residual melanoblasts.

Clinical Presentation and Diagnosis

In a review of 20 cases, Ost and colleagues found the common presenting symptoms of primary pulmonary melanoma to be cough (50%), hemoptysis (40%), and postobstructive pneumonia (25%). Of note, 30% of patients were asymptomatic (the lesion was found incidentally). Constitutional symptoms of weight loss, night sweats, or fever were present in 25% of patients.¹⁵⁰ In addition to the pathologic criteria for the identification of primary pulmonary melanomas, a complete evaluation of the patient must be conducted to rule out any other primary source.

Treatment

If a pulmonary melanoma is encountered and, after a thorough examination, is determined to be a primary lesion, the appropriate treatment is anatomic resection (usually lobectomy) with lymph node dissection.¹⁵⁰

PRIMARY PULMONARY CARCINOSARCOMA

Epidemiology and Pathology

Primary pulmonary carcinosarcomas were once considered to be primary pulmonary sarcomas, but given their varied histologic makeup, these neoplasms now occupy a designation of their own. Carcinosarcomas contain a mixture of carcinomatous and sarcomatous components¹⁵⁵ and generally arise in middle-aged to older adult populations.¹⁵⁵⁻¹⁵⁷

Diagnosis

The presence of cytokeratin and vimentin antibodies can be used to readily distinguish carcinomatous and sarcomatous tumor formation from each other, with the difference in reaction to the tumor markers used to make the diagnosis of a carcinosarcoma.¹⁵⁵ Carcinosarcomas are rarely diagnosed preoperatively. On occasion, diagnosis can be made by cytologic analysis of sputum¹⁵⁸ and, when a nodule is present, by transthoracic needle biopsy.¹⁵⁹

Treatment and Prognosis

Complete surgical resection with clear margins is the most commonly accepted treatment for primary pulmonary carcinosarcomas. Huwer and colleagues¹⁵⁵ have advocated that chemotherapy and radiation (the standard modalities for treatment of soft-tissue sarcoma) should be administered to those with primary pulmonary carcinosarcoma, arguing that the prognosis is largely dependent on the sarcoma component of the tumor.

Given its propensity to metastasize to distant sites and its high rate of local recurrence, primary pulmonary carcinosarcoma has a poor prognosis.^{160,161} Petrov et al¹⁶² reported a 5-year survival of 49%, with a mean survival of 37 months.

SECONDARY LUNG TUMORS

Michael Friscia • Melissa Culligan • Joseph Friedberg

CHAPTER OUTLINE

HISTORY OF METASTASECTOMY

PATHOPHYSIOLOGY OF PULMONARY METASTASES

Do Metastases Metastasize?

Does Lung Cancer Metastasize to Lung?

EVALUATION OF THE PATIENT WITH SECONDARY PULMONARY TUMORS

Symptoms and Presentation

Radiographic Evaluation

Tissue Diagnosis

INDICATIONS FOR SURGERY

SURGICAL APPROACH

LYMPH NODE DISSECTION

CONCLUSIONS

After the liver, the lung is the second most common site for metastatic involvement in neoplastic disease when all tissues and organs are considered, and 20% to 54% of patients with cancer will have pulmonary metastases at some point in the natural history of their disease (Boxes 23-1 and 23-2). In the absence of extrathoracic metastases (i.e., in approximately 25% of patients with disseminated disease), retrospective data have shown that complete resection can be associated with increased survival, regardless of histology, in appropriately selected patients. Cures have been reported with either resection alone or in combination with chemotherapy.^{1,2} Surgical forms of palliation can improve quality of life. For some patients, surgery may have a complementary role, such as defining residual disease that is potentially amenable to salvage forms of therapy or obtaining adequate tissue for molecular testing for targeted therapies.

HISTORY OF METASTASECTOMY

During the 19th century, in the European literature there were sporadic reports of lung resections for metastatic tumors. The first of these reports was in 1855, by the French surgeon Sédillot, who removed a chest wall tumor and excised disease extending into the lung.³ The first case of a true pulmonary metastasectomy was described by Weinlechner in 1882 in a patient with a rib sarcoma,

who was found to have two incidental pulmonary metastases at the time of the sarcoma resection.⁴ Kronlein reported the first long-term survivor after pulmonary metastasectomy in a patient with recurrent chest wall sarcoma and a metastatic lung nodule. The patient went on to survive 7 years, eventually succumbing to recurrent pulmonary disease.⁵⁻⁷

The first, and perhaps most famous, report of a planned pulmonary metastasectomy in the United States was performed in 1933 by Barney and Churchill.¹ Soon after resection of a renal cell carcinoma, they noted that the patient's pulmonary nodule, seen on a chest radiograph preoperatively and presumed to be tuberculosis, had doubled in size. The lesion, now thought to represent metastatic disease, was treated with radiation therapy. They noted a poor response and elected to resect the nodule. The patient went on to live 23 years, eventually dying of coronary artery disease with no evidence of tumor recurrence at autopsy. Despite the early discovery (in the late 1800s) that survival could be improved by resection of metastatic disease, it was not for another 40 years that metastasectomy was performed as a separate procedure by Divis in Europe.⁸ This was followed soon after by similar reports in the American literature by Torek and Tudor Edwards in the early 20th century.^{9,10}

These early reports, and others like them, paved the way toward general acceptance of pulmonary metastasectomy. Although initial indication for surgery was reserved

for those with a solitary metastasis, with time and experience, surgeons began to perform more aggressive metastasectomies. In 1947, Alexander and Haight described the first case series of 24 patients who underwent pulmonary metastasectomy.¹¹ In this series, they described a young woman with a spindle cell neurogenic sarcoma. She initially underwent a right lower lobectomy for metastatic disease in 1939. She had a recurrence in 1940 for which she underwent a left upper lobectomy. This article was the first to define criteria for resection of pulmonary metastases, including control of the primary tumor, absence of extrathoracic disease, and sufficient pulmonary reserve.

The largest effort aimed at evaluating patients undergoing pulmonary metastasectomy was undertaken by the International Registry of Lung Metastases (IRLM). Established in 1991, the IRLM accrued 5206 patients in North America and Europe. This landmark report demonstrated that complete resection, long disease-free interval, and single lesions were associated with better long-term survival. This and other studies have helped to develop current criteria for performing pulmonary metastasectomies and to define anticipated survival after resection.¹²⁻¹⁴

PATHOPHYSIOLOGY OF PULMONARY METASTASES

In 1889, British surgeon Stephen Paget observed that metastatic disease followed a nonrandom pattern. Using autopsy records of patients with a variety of primary tumors, he hypothesized that factors in certain tumors have an affinity for certain factors in target organs. Theories have subsequently evolved that attempt to explain the propensity for metastases to spread to specific organs. The “cascade spread” theory hypothesizes that a single organ represents the first site of spread, followed by systemic dissemination.¹⁵ This metastatic cascade is considered to be a complex series of events culminating in the

generation of metastases. The initial phase of the cascade involves tumor growth via neovascularization, which is stimulated by growth factors secreted by the tumor cells and local host cells. The invasive phase of tumor growth involves the local production and activation of proteolytic enzymes (matrix metalloproteinases, collagenases, serine proteinases, cysteine proteinases) derived from both the host and tumor tissue. These enzymes decrease cell adhesiveness, stimulate cell migration, and enhance chemotaxis and subsequent tumor cell detachment.

Metastasis is most likely initiated after cell detachment from the primary tumor mass. Typically, epithelial cells undergo anoikis (apoptosis) because of the loss of cell-cell interactions once they are separated from parent tissue. Metastatic cells are thought to resist anoikis by forming cell-cell attachments with other tumor cells or host cells and through the overexpression of proteins that inhibit anoikis.

Movement from the extracellular space into a vascular compartment is termed *intravasation*. Cancer cells have been shown to degrade basement membranes via local release of extracellular matrix-degrading proteins (matrix metalloproteinases), facilitating migration into the lymphatic and circulatory system. Once in the circulatory system, tumor cells must avoid recognition and destruction by the host immune system. Only 0.1% of tumors cells in circulation go on to generate metastases.¹⁶ Mechanisms that cancer cells use to survive include human leukocyte antigen (HLA) class I downregulation (mediator of immune cell recognition) and loss of immunogenic antigens. Cancer cells also downregulate the immune system via the production of immunosuppressive cytokines. Some evidence suggests that clots form around tumor cells that protect these cells from immunologic and physiologic stresses in the bloodstream.¹⁷

Tumor cells bind to pulmonary vasculature, which, via a platelet-induced reaction, stimulates endothelial cell retraction.¹⁸ The lung is thought to play a role as the primary capillary filter for drainage of most organs, and its rich capillary network provides an ideal environment for deposition. Movement of tumor cells from the circulatory system into the interstitium is called *extravasation*. Basement membrane disruption is thought to occur in a manner similar to intravasation.

Once extravasated, tumor cells may remain quiescent or they may proliferate. Proliferation and local invasion require neovascularization, which is induced via a shift toward the intracellular and extracellular production of pro-angiogenic factors. Epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and transforming growth factor- α (TGF- α) foster tumor cell proliferation in the new environment. On the other hand, the host organ produces inhibitors, such as TGF- β , mammastatin, and amphiregulin, to prevent metastatic implantations.¹⁹ These compounds are under investigation to assess their ability to control metastatic disease.

Do Metastases Metastasize?

It is thought that metastases need to follow the same steps as the primary tumor to metastasize: angiogenesis, intravasation, arrest, and extravasation. In 1975, Hoover and

Ketcham demonstrated, experimentally, that metastases do have the ability to metastasize.²⁰ In this experiment, the primary tumor in mice was amputated after pulmonary metastasis developed. These mice were then placed into parabiosis with normal syngeneic partners. Metastases were demonstrated in the non-tumor-bearing partners, supporting the theory that metastases can re-metastasize. In addition, both autopsy and experimental data have defined the concept of metastases from metastatic disease.²¹ Further support of this concept is provided by the presence of intrathoracic lymph node metastases among patients who undergo anatomic resection and lymph node dissection for metastatic lung disease, especially for renal cell carcinoma (46.6%)²² and colon cancer (9.8%).²³ On the other hand, Sugarbaker and colleagues took pieces of healthy lungs and transplanted them into mice that had established pulmonary metastases. Their results demonstrated no evidence of secondary tumor development, thus leading to the conclusion that metastases do not metastasize.²⁴

Whether metastases metastasize is still poorly understood and remains a challenge for medical oncologists and surgeons as they struggle to determine the best treatment and the proper timing of that treatment for patients with pulmonary metastases.²⁵

Does Lung Cancer Metastasize to Lung?

Lung cancer can metastasize via lymphatic channels to the ipsilateral lung and, as suggested by some autopsy series, less commonly to the contralateral lung. These are patients with one primary lung cancer and intrapulmonary metastases. According to the seventh revision of the lung cancer staging system of the International Association for the Study of Lung Cancer (IASLC), ipsilateral nodules in the same lobe as the primary tumor will be considered T3 and nodules in a different ipsilateral lobe from the primary tumor will be considered T4.²⁶ It is difficult, however, to determine if these patients have synchronous lesions or a primary lung cancer with intrapulmonary metastases. Ichinose and coworkers have used DNA flow cytometry to evaluate these lesions.^{27,28} Using this technique, lesions are determined to be synchronous if they demonstrate completely different DNA ploidy. If both tumors show diploidy, or when at least one DNA index of abnormal clones between two aneuploidy tumors is the same or almost identical, they are considered metastatic. In addition, loss of heterozygosity and p53 mutational status have been used to distinguish multicentric lung cancers from intrapulmonary metastases.^{29,30} Using these criteria, it appears that lung cancer can metastasize to lung, albeit less commonly than synchronous tumors.

EVALUATION OF THE PATIENT WITH SECONDARY PULMONARY TUMORS

Symptoms and Presentation

Because approximately 75% to 90% of patients with secondary pulmonary malignancies are asymptomatic, their disease is most commonly discovered incidentally on

routine or follow-up radiologic examinations.^{31,32} Absence of symptoms is predominantly due to the usual peripheral location of pulmonary metastases. The asymptomatic nature of pulmonary metastases makes necessary the practice of obtaining lung-imaging studies in the follow-up of most cancer patients.

Symptoms, when they do occur, typically occur with endobronchial or pleural involvement, large bulky disease, or central venous obstruction. Patients may have symptoms of cough and hemoptysis suggesting an endobronchial lesion and thus warrant bronchoscopic examination. Endobronchial metastatic lesions are extremely rare in patients who die of solid tumors, with breast, kidney, pancreas, colon, and melanoma as the most common sources.³³ Dyspnea may occur, which is usually secondary to airway obstruction, a pleural effusion, extensive parenchymal replacement by multiple metastatic lesions, or lymphatic spread. Finally, chest pain, wheezing, or pneumothorax may occur, but these are unusual presenting symptoms.

During physical examination, wheezing may be heard, which is a sign of airway obstruction. Occasionally, a pericardial rub is heard, representing pericardial involvement. Pleural or pericardial involvement is usually the result of ovarian, breast, or lung adenocarcinomas. Thymic malignancies are notorious for pleural involvement when they metastasize.³⁴ In addition, decreased breath sounds and egophony may be appreciated when an obstructing lesion is present with associated lobar or segmental atelectasis, which could be seen on a chest radiograph as postobstructive pneumonia.

Radiographic Evaluation

Most pulmonary metastases are detected by chest radiography (Fig. 23-1) or computed tomography (CT) (Fig. 23-2) during routine follow-up for the primary cancer. Radiologic testing is used to define the extent of the disease and to determine whether an individual is a candidate for pulmonary metastasectomy. A search for extrathoracic disease may involve imaging the original primary disease site as well as looking for distant disease. A new pulmonary nodule in a patient with a prior malignancy should be considered cancer until proven otherwise.

Because of its higher resolution, helical CT is the gold standard imaging modality for evaluation of the lungs and characterization of metastatic lesions. Lung metastases can be small (usually less than 1 cm), and they appear as multiple lesions in 75% of cases. Most metastatic lesions to the lung are found on the lung periphery, and they have a predilection for the basilar lung fields, probably because of increased blood flow to this region when the patient is in an upright position.^{35,36} Distinguishing between a metastatic lesion and other malignant or benign lung lesions can be difficult. CT characteristics of metastatic lesions include spherical shape with well-circumscribed, smooth borders. Lesions with irregular or spiculated borders with associated linear densities are more commonly associated with primary lung cancers, although this is not a universal finding.³⁵ Calcifications in lung nodules are rarely seen in metastatic pulmonary disease. Metastases that may have associated calcifications

FIGURE 23-1 ■ Pulmonary metastases as detected by chest radiography. **A**, Left lower lobe metastasis. **B**, Left upper lobe metastasis.

include osteosarcomas, chondrosarcomas, and breast and ovarian cancer. Cavitation can occur in benign lesions such as those caused by lung abscess, aspergillosis, or tuberculosis. Malignant nodules that can cavitate include squamous cell carcinoma (primary lung or metastatic carcinomas), sarcoma, and testicular tumors.

Positron emission tomography (PET) is imperative when considering patients for metastasectomy. In a series of patients with melanoma, ^{18}F -fluorodeoxyglucose (FDG)-PET had a sensitivity of 92%, a specificity of 88%, and accuracy of 91%.³⁷ PET is helpful in assessing extent of disease, including the primary disease site as well as thoracic and extrathoracic potential sites of metastases. However, PET positive findings should be interpreted with caution because of the low specificity of positive results. When considering surgical management of metastatic lung disease, all potential sites of metastatic disease identified on CT and PET should be thoroughly evaluated, particularly in the mediastinum, because tissue confirmation of multiple organ involvement will likely change management. Although CT is useful for identifying and characterizing pulmonary metastases, caution must be exercised because intraoperative pulmonary palpation may identify smaller parenchymal lesions not detected with imaging.

FIGURE 23-2 ■ Pulmonary metastases as detected by chest CT. **A**, Metastatic lesion in the right upper lobe. **B**, Metastatic lesion in the superior segment of the right lower lobe.

Tissue Diagnosis

Multiple nonsurgical options are available for confirmation of a histologic diagnosis. These options, including endoscopic procedures and percutaneous needle aspiration, should be used when management will change based on the results. This is particularly true for patients that are borderline surgical candidates or who refuse surgery but desire alternative treatment.

Sputum cytology is of historical interest and has been replaced by bronchoscopy, as it is often nondiagnostic because of the peripheral location of most pulmonary metastases.³⁸ Bronchoscopic examination and diagnosis of pulmonary metastases is useful in the case of endobronchial or centrally located lesions. Peripheral radial ultrasound probes or electromagnetic guidance systems may increase the yield of endobronchial sampling. Percutaneous fine-needle aspiration (FNA) is another option for obtaining a tissue diagnosis. It is associated with a risk of pneumothorax, in some series as high as 27%.³⁹ Unfortunately these procedures are plagued by low sensitivity, such that equivocal or “negative” results do not establish a diagnosis of benign disease. In addition, in the current era of molecular and genomic testing, obtaining ample tissue for processing with these less invasive techniques can be difficult and could require multiple procedures. If tissue diagnosis is desired but less invasive means have failed to obtain adequate tissue, video-assisted thoracic

surgery (VATS) with excisional biopsy is recommended. VATS has a sensitivity and specificity approaching 100%.⁴⁰⁻⁴² It is a more invasive procedure than FNA and requires general anesthesia with selective lung ventilation. Also, when extent of metastatic disease is limited, it may be therapeutic as well as diagnostic, as the nodules can be completely excised. Occasionally, there is a role for thoroscopic core needle biopsy, such as in cases of multiple lesions not amenable to complete surgical resection when treatment hinges on a tissue diagnosis and all less-invasive diagnostic modalities have proved fruitless or are deemed less safe than a VATS approach.⁴³

Because the pretest probability of malignancy is high in a patient with a lung nodule and history of malignancy, the negative predictive value is low if cancer is not identified on a specimen obtained percutaneously or with bronchoscopy.⁴⁴ For this reason, nonsurgical procedures aimed at obtaining a histologic diagnosis should be used selectively, and multidisciplinary evaluation with a surgeon and oncologist is of the utmost importance. In this setting, diagnostic procedures can be selected based on risk profile, local expertise, and anatomic location of the lesion with the aim of proceeding to an appropriate therapy.

INDICATIONS FOR SURGERY

Reasons to perform surgery for secondary pulmonary malignancy include curative resection, tissue diagnosis, or evaluation of residual disease. Before proceeding with resection, a number of questions should be considered in the preoperative assessment of the patient.

Does the pulmonary nodule represent one site of multiorgan spread, thereby contraindicating resection? Pulmonary metastases are common in the advanced stages of cancer, with as many as one third of patients presenting with secondary nodules. Of these patients, however, most pulmonary nodules (75% to 85%) are a manifestation of widespread disease. Consequently, only 15% to 25% of patients have lesions confined to the lung and are appropriate candidates for curative resection (Table 23-1). Preoperative evaluation, therefore, should exclude extrathoracic disease.

When pleural or pericardial effusion is present, thoracentesis or pericardiocentesis should be performed to

evaluate for malignancy. Positive cytology contraindicates resection. Cytology may be falsely negative, however, in up to 40% to 60% of cases.^{45,46} Consequently, a negative cytology returned in the context of a high index of suspicion for malignant effusion warrants pericardial or pleural biopsy, or both. A VATS approach can be used to access the pleural space, and it offers a minimally invasive transthoracic approach to the pericardium. It also affords the option of visualizing and palpating the lung as well as sampling the mediastinal lymph nodes. Bronchoscopy should always be performed before thoracoscopy or thoracotomy, to evaluate for endobronchial lesions.

Is a nonsurgical therapeutic option available? Although surgical resection of secondary pulmonary malignancies may give patients a significant survival advantage, nonsurgical management may be more appropriate for certain cancers. For example, in the context of nonseminomatous germ cell tumors, great success has been obtained with chemotherapy, with cure rates approaching 90% (see “[Germ Cell Tumors](#),” later). In addition, alternative therapies such as radiofrequency ablation or stereotactic body radiation may be appropriate in selected cases (see “[Alternative Treatment Options](#),” later).

Will the patient tolerate the procedure? Risk factors associated with metastatic disease (e.g., smoking and advanced age) require that patients being considered for surgical resection receive a thorough medical assessment with particular attention to their pulmonary and cardiac status. Stress testing, echocardiograms, arterial blood gases, pulmonary function testing, and ventilation-perfusion scans may be necessary to assess patients’ tolerance for a proposed resection or their ability to undergo single-lung ventilation. Also, previously administered chemotherapeutic agents such as bleomycin or mitomycin may result in additional compromise of pulmonary function, and doxorubicin may be associated with cardiac impairment. In addition, the thoracic surgeon expecting to perform a metastasectomy must always be prepared to perform a formal lobectomy should the pathology reveal a primary lung cancer or should wedge resection result in incomplete resection. Thus, performing the preoperative assessment with consideration for anatomic resection and its attendant risk is prudent.

Are the lesions resectable? *Unresectability* is defined as noncontiguous involvement beyond the visceral pleural

TABLE 23-1 Most Common Site of Metastasis and Percentage with Isolated Disease

BOX 23-3 Selection Criteria* for Metastasectomy

- Local control of the primary tumor or ability to completely resect the primary with synchronous presentations²⁰
- Radiologic findings consistent with metastatic disease
- Absence of extrathoracic metastases (i.e., metastasis is confined to the lung)
- Ability to perform a complete resection of the metastases
- No significant comorbidity that would preclude surgery
- No alternative therapy that is superior to surgery

*Approximately one third of patients with metastatic disease meet these criteria.

envelope.³¹ This is best determined at operation. Preoperatively, imaging modalities can only provide an estimate of resectability. In addition, thoracoscopy can sometimes be useful to assess for disseminated disease or bulky tumors that involve major structures and preclude complete resection. If the pericardium or pleura is involved with neoplastic disease from direct extension of an underlying parenchymal lesion, but there is no associated effusion, they should be resected en bloc with the specimen. Direct metastases to the pleura or pericardium in a discontinuous manner (i.e., disseminated spread) and malignant pleural or pericardial effusions are generally contraindications for resection.

Is the primary tumor controlled? Efficacy of pulmonary metastasectomy depends on, among other factors, the ability to control the primary site of disease. The primary neoplasm should generally be addressed before resection of the pulmonary metastases. Therefore, thorough preoperative testing should be performed to rule out other possible metastatic sites or local recurrence of the primary tumor prior to pulmonary metastasectomy (Box 23-3).

Alexander and Haight, in the 1940s, were the first to describe specific selection criteria for consideration of pulmonary metastasectomy. They realized that the benefits of surgical resection depended on primary tumor control, absence of extrathoracic spread, and adequate patient selection. Approximately one third of patients meet these selection criteria and can appropriately undergo metastatic resection.

SURGICAL APPROACH

Surgery for pulmonary metastases is based on the principle of performing a complete resection while preserving as much lung tissue as possible.⁴⁷ The specific location of the tumor in the lung plays a role in determining the resection volume necessary to remove all disease. Wedge resection of the lung to include a negative resection margin is the standard therapy. Deeply located lesions or central lesions may require an anatomic resection—segmentectomy, lobectomy, or, in rare cases, pneumonectomy.

Bronchoscopy is performed routinely at the time of resection to exclude endobronchial involvement, which

may alter surgical approach or preclude resection with curative intent. Epidural analgesia has become the gold standard in thoracic surgery for managing postoperative pain and facilitating postoperative secretion clearance, particularly when thoracotomy is required. Single-lung ventilation using a double-lumen endotracheal tube or a bronchial blocker allows the surgeon to perform a thorough manual inspection of the superficial and deep parenchyma of the deflated lung. An articulating stapler that cuts and staples simultaneously is useful for removing palpable nodules while sparing lung tissue. A 1-cm margin is considered adequate when excising metastases to the lung, but this has not been systematically evaluated.

The choice of incision should reflect the extent of disease, the goal of complete resection, and the patient's ability to undergo the procedure. The surgical options for metastasectomy include VATS, thoracotomy, and midline approaches (which allow simultaneous access to both thoracic cavities). VATS procedures typically involve two- or three-port access to the pleural space, ipsilateral lung collapse via a double-lumen tube with digital palpation of the lung, and nodule localization through the nearest trocar site. Central lesions may be difficult to palpate through the smaller incisions, which may justify an open procedure for their removal. In addition, direct bimanual palpation, which is difficult with VATS, may aid in identification of additional lesions not seen on imaging. In 1996, McCormack and colleagues prospectively performed VATS resections based on CT findings, followed by thoracotomies with lung palpation, and found additional lesions in 14 of 18 patients.⁴⁸ Cerfolio and coworkers confirmed that 64-slice helical CT scan missed pathologically proven metastases in 18% of cases when thoracotomy with bimanual palpation was performed.⁴⁹ Other studies have shown that, at least for patients who underwent metastasectomy for colorectal cancer, there is no statistically significant difference in survival between the open and the thoracoscopic approaches.⁵⁰ Lin and colleagues reported on 99 potentially curative resections of metastases using a VATS approach and demonstrated long-term survival comparable to historic results with an open approach.⁵¹ Landreneau and coworkers observed less pain and a shorter hospital stay after VATS resection of colorectal metastases to the lungs.⁵² Furthermore, as CT scanning technology evolves, the detection of nodules as small as 1 mm may be achieved, further narrowing the disparity between CT scanning and manual palpation.⁵³ At this point, the data support thoracotomy and manual palpation as being the more sensitive method for detecting nodules. However, the choice between thoracotomy and VATS involves many factors and should be individualized for every patient.

Open approaches include standard thoracotomy, bilateral simultaneous or staged thoracotomy, a clamshell and hemi-clamshell incision, and median sternotomy. Standard thoracotomy can be performed as the definitive procedure in patients with unilateral disease or as a staged procedure, with a contralateral thoracotomy performed approximately 6 weeks later in patients with bilateral disease. Bilateral submammary incisions including a transverse sternotomy (a clamshell incision) are useful for

accessing both thoracic cavities for metastasectomy. A hemi-clamshell incision, consisting of a unilateral anterior thoracotomy with a partial or complete sternotomy, has been described. Each of these incisions may at times be the correct approach, but, generally, each of them tends to be more morbid and painful than VATS or a median sternotomy. Morbidity and mortality rates for lung metastasectomy by conventional means range between 0% and 31.6% and between 0% and 7.6%, respectively.⁵⁴

Median sternotomy, preferred by some surgeons, provides access to both thoracic cavities, but it provides limited exposure to lesions in the left lower lobe and large posterior central lesions. Patients with a history of radiation therapy, obesity, chronic obstructive pulmonary disease, diabetes, and steroid use may be at higher risk for wound complications after median sternotomy.

The metastasectomy itself usually consists of a wedge resection. This is facilitated by the tendency of metastatic disease to be found at the periphery of the lung, and it is easily performed with lung clamps and a pulmonary stapling device. Excision with electrocautery or laser may also be performed under select circumstances.⁵⁵⁻⁵⁸ Posterior areas of the lung may be better assessed by filling the hemithorax with saline to float the lung anteriorly. Resection with a 1- to 2-cm margin of uninvolved tissue is adequate in this setting. Lobectomy is indicated if a lesser procedure would result in an incomplete resection or is not technically possible. This is most commonly the case with large, centrally located lesions or lesions in such close proximity to bronchovascular structures that an anatomic resection is required to avoid leaving fatally compromised lung tissue behind. Chest wall resection of contiguous lesions not associated with other disease, or even pneumonectomy, has been shown to improve survival when used in the appropriate setting.^{3,59,60}

When considering surgery for the treatment of presumed (based on preoperative imaging) unilateral pulmonary metastases, one must consider whether this approach will miss undiagnosed contralateral disease and whether this would be detrimental to the patient. One study tried to answer this question by comparing sternotomy to unilateral thoracotomy in patients with metastases that appeared unilateral in preoperative imaging studies.⁶¹ Unilateral thoracotomy was used, and the contralateral lung was not assessed. One might expect residual disease in the unevaluated thorax, resulting in a worse prognosis for this group. In fact, no difference in long-term survival was found. Furthermore, repeat resection of recurrences have been shown to improve survival, thus making the argument that any missed subclinical disease could be resected subsequently.^{61,62} These results have been corroborated by Younes and colleagues.⁶³ In this study, patients undergoing unilateral thoracotomy for unilateral disease ($n = 179$) and patients undergoing bilateral thoracotomies for bilateral disease ($n = 88$) were investigated. The two groups of patients with confirmed bilateral metastases (synchronous or metachronous) were compared. Patients who experienced recurrence in the contralateral lung within 3, 6, or 12 months had overall 5-year survival rates of 24%, 30%, and 37%, respectively. When patients with recurrence in the contralateral lung

were compared with patients with bilateral metastases on admission, there was no significant difference in overall survival. The only two predictors of contralateral recurrence were histology and the number of pathologically proven metastases. Younes and colleagues concluded that bilateral exploration of unilateral lung metastases is not warranted in all cases.

LYMPH NODE DISSECTION

The role of systematic lymph node dissection performed during pulmonary resection for metastases is not well defined. Many studies do not include nodal data because traditionally a lymph node dissection was not routinely performed as part of the operation. The reported incidence of mediastinal nodal metastases varies according to histology.^{14,64} In patients undergoing metastasectomy for renal cell carcinoma, intrathoracic lymph node involvement can be as high as 46.6%.²² Alternatively, Putnam and coworkers demonstrated a very low incidence of lymph node metastases in patients with sarcomatous pulmonary metastases.⁶⁵

There is evidence that the presence of nonsarcomatous lymph node metastases at the time of metastasectomy has an adverse effect on survival, which suggests preoperative identification of mediastinal nodal metastasis may lead one away from a surgical approach.⁶⁴ In addition, the omission of lymphadenectomy from the surgical resection of metastases may incorrectly classify patients as being free of disease. Furthermore, lymph node involvement may influence the ensuing postoperative treatment plan

RESULTS OF PULMONARY METASTASECTOMY

Pulmonary metastasectomy in appropriately selected patients has been shown in retrospective studies to improve survival. When all histologies are considered, the 5-year survival rate for patients undergoing resection of secondary pulmonary malignancy is 25% to 40% (Table 23-2). Many series have evaluated potential prognostic indicators to more clearly define the patients who are most likely to benefit from metastasectomy. For example, short tumor doubling time is frequently a sign of an aggressive lesion, and it has been proposed that patients with these tumors, therefore, might not derive a survival benefit from resection. The results seen in these studies, however, have not been conclusive.⁶⁶⁻⁶⁹ Moreover, the practical application of such a measurement is difficult. Disease-free interval has also been studied in an attempt to predict outcomes. Longer disease-free interval, however, has not been consistently associated with a better prognosis.^{65,69-71} It is not clear whether there is a number of nodules above which resection is unwarranted. As many as 20 to 30 metastasectomies have been performed at one operation with good results.⁷² Thus, multiplicity may be more appropriately used to assist in the assessment of tumor resectability. None of these criteria for predicting positive outcome from metastasectomy has

TABLE 23-2 Five-Year Survival Rates of Various Histologic Metastatic Resections

Histology	5-Yr Survival Rate without Metastasectomy (%)	5-Yr Survival Rate with Metastasectomy (%)

TABLE 23-3 Prognostic Factors in Metastasectomy

Absolute	Equivocal
Complete resectability	Tumor doubling time Disease-free survival Number of nodules Histology Nodal status

been universally established. Most studies have proposed that complete resectability is the only universal determinant of prognosis across histologies (Table 23-3).

Many of the aforementioned studies attempting to evaluate prognostic determinants in pulmonary metastasectomy have been faulted because they lack sufficient statistical power to demonstrate clinical significance. One group, however, reported 5206 cases of pulmonary metastases from various sites from the 18 medical centers of the International Registry of Lung Metastases. In this retrospective review, three indicators were shown to have prognostic significance regardless of primary histology: resectability, a disease-free interval of greater than 36 months, and solitary versus multiple lesions. As a result, the authors proposed a four-group staging system based on the number of prognostic indicators present in a given patient (Table 23-4). Although staging systems such as this may better define the patients most likely to benefit from metastasectomy, survival rates after surgery, even with poor prognostic indicators, may be better than after any other treatment. Consequently, some surgeons believe that metastasectomy should be offered to appropriate patients regardless of these factors, with the possible exception of inability to perform complete resection.¹⁴

In addition to the aforementioned factors equivocally associated with prognosis, other factors have been shown to clearly not affect outcome. These factors include unilateral (as opposed to bilateral) disease, age, sex, and wedge resection versus formal lobectomy (Box 23-4).

After complete pulmonary resection of metastatic disease, recurrence is the most common cause of death. Despite this, repeat resections have contributed to prolonged survival for a number of histologies.^{62,65,73,74} The most studied histology is soft tissue sarcoma. For example,

TABLE 23-4 Prognostic Staging System

Prognostic Stage	Number of Prognostic Indicators*	5-Yr Survival Rate (%)
Stage I	None	61
Stage II	Two	34
Stage III	Three	24
Stage IV	Unresectable	14
